1

The Scope of Modern Anesthetic Practice

KATE LESLIE, LARS I. ERIKSSON, JEANINE P. WIENER-KRONISH,
NEAL H. COHEN, LEE A. FLEISHER, and MICHAEL A. GROPPER

KEY POINTS

- The scope of modern anesthesia practice includes preoperative evaluation and preparation; intraprocedural care; postoperative care including acute pain management; critical care, resuscitation, and retrieval; chronic pain management; and palliative care. Anesthesia plays a key role in health service delivery and has a significant impact on population health and the burden of disease.
- Global and national forces for change include changing patient populations, locations of care, workforce, costs, quality and safety initiatives, research capability, and the availability of data. These forces have major implications for the delivery of care, evaluation and organization of the anesthesia practice, and education and training of physician anesthesiologists.
- The volume of patients presenting for perioperative and obstetric care continues to grow. Increasingly more patients at extremes of age are requiring anesthesia services. Many of the patients are elderly and have significant comorbidities, including obesity and opioid use disorder. This has important implications for delivery of care and health system issues.
- Anesthesia care is shifting from the traditional surgical suite to other procedural areas, ambulatory sites, office-based facilities, and home environments. As anesthesia care expands, anesthesiologists must focus on maintaining the safety and quality of care in these diverse settings.
- Global and regional deficits in the availability of high-quality anesthesia care must be managed by improving the supply of both physician and non-physician anesthesia providers, by better use of technology, and by limiting demand through health promotion and disease prevention strategies.
- Internationally, the costs of health care continue to escalate; unfortunately the increased spending has not consistently translated into improved health outcomes. Health policy initiatives including alternative approaches to healthcare financing and payment systems are increasingly being implemented to encourage efficient and effective team-based anesthesia care.
- Anesthesiology was among the first medical specialties to focus on improving the safety of patient care. As anesthesia has become safer, attention has intensified on quality improvement, a process designed to improve patient experience and outcomes through systematic change and evaluation.
- Basic, translational, clinical, and implementation research is vital to continuous improvement in outcomes. Opportunities to optimize care are supported by the availability of large datasets generated using electronic health records as well as novel analytic techniques. These changes create new opportunities for anesthesiologists to collaborate with basic and translational scientists to better understand current practices and define better ways to deliver care. As always the provision of resources to support these research initiatives is a challenge.
- The scope of modern anesthetic practice is continually expanding and changing. The changes occurring in health care in the 21st century create opportunities for anesthesiologists to assume a broader role in clinical practice and health policy, providing exciting opportunities for the next generation of physicians in our specialty.

Introduction

Anesthesia is fundamental to the overall practice of medicine worldwide. Hundreds of millions of patients receive anesthesia care each year in association with a wide range of medical, surgical, and obstetric procedures. In addition to direct delivery of anesthesia to patients undergoing a surgical procedure, the scope of anesthesia practice extends beyond the traditional surgical suite to include preoperative evaluation and management of underlying clinical conditions (see Chapter 31); postoperative care including acute pain management (see Chapter 81); critical care, resuscitation, and retrieval (see Chapter 67); chronic pain management (see Chapter 51); and palliative care (see Chapter 52). Anesthesia therefore plays an essential role in health service delivery (see Chapter 3) and has a significant impact on global health and the burden of disease (see Chapter 2). The purpose of *Miller's Anesthesia* is to cover the full scope of contemporary anesthesia practice, from fundamental principles to advanced subspecialty procedures.

Every edition of this textbook begins with comments about the novel diagnostic and therapeutic procedures that have been developed since the last edition and the increasing complexity of patients presenting for anesthesia and perioperative care, especially those at the extremes of life. Each edition also provides descriptions about advances in anesthesiology that have facilitated patient care, including improved understanding of the processes that underlie disease and injury, the increasing sophistication of the pharmacologic and technical resources available, and the improvements in systems designed to promote safety and quality in health care. The 9th edition is no exception: in the last decade the advances in anesthesia and surgical care, especially for patients receiving complex clinical care, have been truly remarkable.

None of these advances would have been possible without the commitment of anesthesiologists to leadership, teaching, and research. Evidence of their contributions can be found in every chapter of the book, extending from improved understanding of the mechanisms of anesthesia and the processes that regulate organ function and drive organ failure; through new technologies, drugs, and systems of care and education; to improved understanding and acknowledgement of the critical role patients and their families play in decision making about healthcare and end-of-life issues.

The future of anesthesiology is filled with opportunities and challenges. Global and national forces will drive evidence-based, cost-effective perioperative and obstetric care by multiprofessional and multidisciplinary teams. These changes will be supported by integrated electronic medical records and large databases and registries of healthcare outputs and outcomes. Increasingly, anesthesia care has expanded outside the operating room, into preoperative clinics, intervention suites, extended postanesthesia care units, and even into patients' homes. As is true for other medical specialties, anesthesiologists have adopted telehealth strategies to extend the care provided to patients and colleagues beyond face-to-face encounters. Technological advances have and will continue to facilitate less invasive interventions and improved anesthesia delivery and monitoring systems. As a result, seriously ill and injured patients and those at the extremes of age, often with associated comorbidities now have access to care previously not available to them. Care is also becoming more personalized, in large part because of the availability of genetic testing and an improved understanding of the unique needs of each patient based on disease severity and his or her probability of responding to specific treatment modalities. Partially as a result of these improvements in care, the costs of caring for an aging population with progressively sophisticated therapies challenge all nations. These forces will likely have a major effect on the scope of perioperative care in general and anesthesia services in particular. Therefore, anesthesiologists must be involved in health policy decisions about the distribution of resources and the need for high-quality evidence to guide practice. In the rest of this chapter we will deal with some of these forces in detail.

Forces That Will Change Practice (Fig. 1.1)

CHANGING PATIENT POPULATIONS

The volume of patients having surgical procedures each year is large and growing. In 2012, more than 300 million patients had surgery worldwide.[1] This number probably underestimates the overall volume of patients requiring anesthesia services, in large part because much of anesthesia care is now provided outside of traditional surgical suite environments. Global initiatives aimed at delivering universal health coverage and safe and affordable surgery and anesthesia care will result in further increases in the number of patients requiring anesthesia care in coming decades (see Chapter 2).

Increasingly many of the patients requiring anesthesia services will be older and have multiple health problems, including obesity and chronic pain associated with opioid use.

The World Health Organization has estimated that by the year 2050 nearly one-quarter of the world's population will be over 60 years of age.[2] In the United States the number of people aged 65 years and over, and therefore eligible for treatment under Medicare, is expected to exceed 78 million by 2030. In high income countries the increase in the numbers of older patients will result from improved preventative care and management of chronic disease and injury. In low- and middle-income countries this change will result from improvements in maternal and child health and the eradication or control of infectious diseases. Concurrently, improvements in anesthetic and surgical care in many countries are increasing medical care options for older patients, who are now receiving more surgical services—many complicated procedures—than ever before. However, the accessibility of these additional options is presenting new challenges for both patients and providers. Aging is associated with a decline in physiologic reserve and organ function and an increase in the risk of disease, injury, and disability (both physical and cognitive). The aging process is highly variable, with significant influence from genetic, environmental, and societal factors. Aging is also associated with considerable changes in social and economic circumstances. Overall these factors lead the older adult to greater dependence on health and social care and challenges in the provision of safe surgery and anesthesia (see Chapters 65 and 82).

One significant public health issue that is accelerating internationally is obesity. It has emerged as a global health epidemic. In 2016, 39% of adults and 18% of children and adolescents worldwide were overweight.[3] In the United States the prevalence of overweight populations was 67.9% and 41.8% in adults and children, respectively. Although the rate of increase in the number of overweight and obese populations have slowed in some high-income nations, this is not the case in low- and middle-income countries. Poor access to healthy diets and limited exercise contribute to the problem. Obesity is associated with an increased burden of disease and injury, including diabetes and hypertension that result in the need for more interactions with the health system, high costs, and significant challenges in the provision of safe and high-quality surgical and anesthetic care (see Chapter 58).

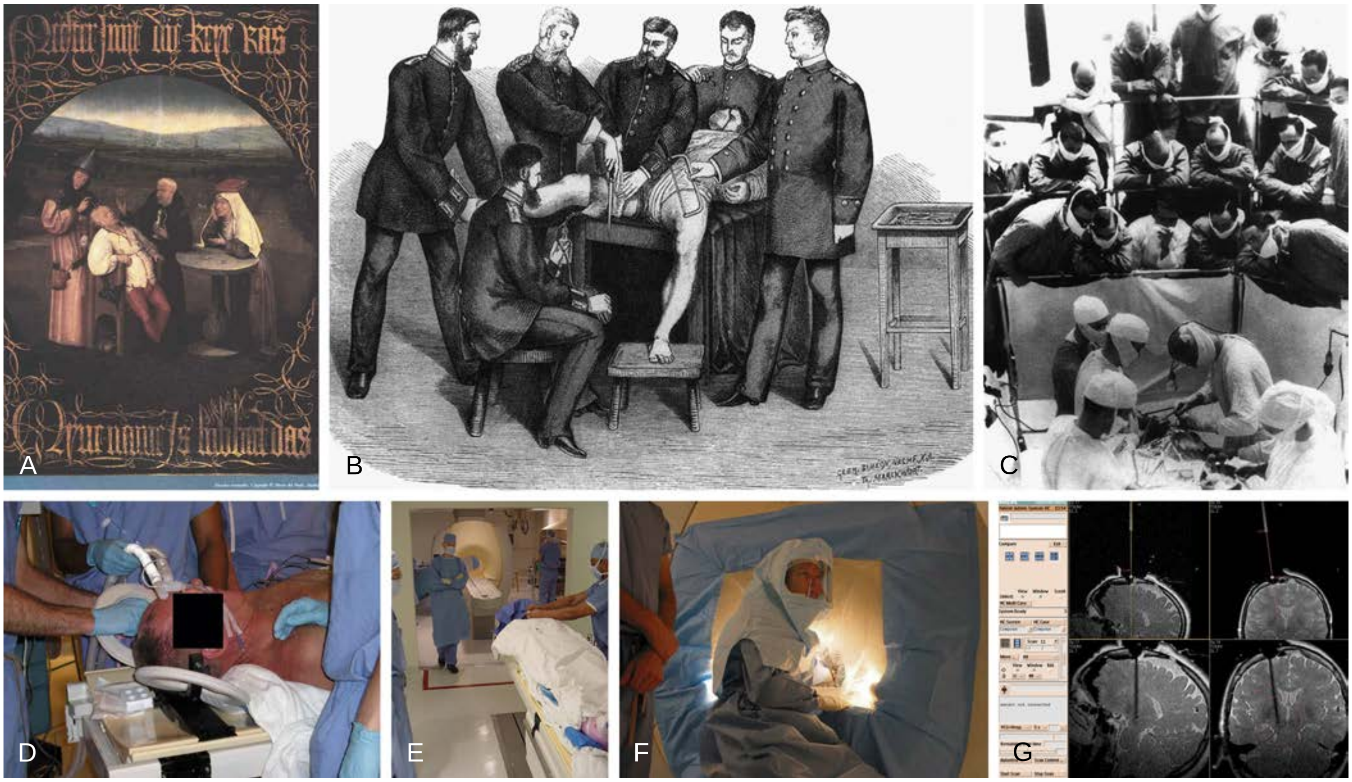

Fig. 1.1 Changing scope and settings of anesthesia and perioperative medicine. (A) *The Cure of Folly,* by Hieronymus Bosch (c.1450–1516), depicting the removal of stones in the head, thought to be a cure for madness. (B) Friedrich Esmarch amputating with the use of anesthesia and antisepsis. (C) Harvey Cushing performing an operation. The Harvey Cushing Society is observing (1932). (D) Placement of a deep brain stimulator for the treatment of Parkinson disease using a real-time magnetic resonance (MR) imaging technology (MR fluoroscopy). The procedure occurs in the MR suite of the radiology department. The patient is anesthetized and (E) moved into the bore of the magnet. (F) A sterile field is created for intracranial instrumentation, and (G) electrodes are placed using real-time guidance. (A, Museo Nacional del Prado, Madrid. Pain management strategies have also had impact on anesthesia practice and perioperative care. The current opioid epidemic arose from increased prescription of opioid drugs to treat all types of acute and chronic pain, including postoperative pain. This crisis has been exacerbated by diversion of prescribed medication (i.e., diverting a medication from its original licit medical purpose) and use of "street" drugs, including opioids. The consequences are significant for individual patients and society as a whole. Opioid use has resulted in addiction, overdoses, homelessness, excessive emergency room visits, increased infections, and neonatal abstinence syndrome. The Centers for Disease Control and Prevention (CDC) estimated that more than 191 million prescriptions (58.7 prescriptions per 100 persons) were filled in the United States in 2017, with marked regional variation characterized with adverse physical, economic, and social circumstances.[4] Opioids were involved in 42,249 overdose deaths in 2016 (66.4% of all drug overdose deaths). The situation is similar in other nations, with the World Health Organization estimating that 27 million people worldwide suffered opioid use disorder in 2015.[5] Recent government action has been substantial, particularly in the United States. The Department of Health and Human Services has implemented a five-point plan to combat the crisis including: (1) improved access to prevention, treatment, and recovery support services; (2) targeted availability and distribution of overdose-reversing (narcotic antagonist) drugs; (3) strengthened public health data reporting and collection; (4) support for cutting-edge research on addiction and pain; and (5) advances in pain management practice.[6] As experts in the pharmacology and clinical use of opioid drugs (see Chapters 24, 51, and 81), anesthesiologists and pain medicine specialists have and must continue their essential role in resolving this crisis.

CHANGING LOCATIONS OF CARE

Anesthesia practice has expanded to a variety of locations. A number of factors account for this shift in anesthesia and perioperative care (see Chapter 73). The costs of traditional operating room care are high and the services available may be unnecessarily comprehensive and complex for the planned episode of care. With advances in clinical care, the need for inpatient perioperative care is reduced for many surgical procedures. As a result more and more procedures are being performed in hospital outpatient settings, ambulatory surgery centers, and office-based practices. The focus of accrediting bodies and anesthesiology societies has been on maintaining the safety and quality of anesthesia care in outpatient settings, including providing for extended admission and escalation of care when clinically necessary to ensure patient safety.[7] At the same time, the payment models have not necessarily kept pace with these advances in clinical care. In the United States, the growth in nonhospital-based care has occurred despite curbs in reimbursement for ambulatory surgery by governmental and private payers.

The clinical practice for surgical patients has also changed because of changes in sites of care and inpatient management. For most patients, many aspects of perioperative care have shifted from the hospital or other healthcare facility to outpatient or home settings. As one example, the elimination of preoperative hospital admission to day-of-surgery admission is virtually complete in high-income nations. Hospital lengths of stay are also much shorter. As a result, postoperative care is increasingly undertaken in the home as well, often as part of enhanced recovery after surgery programs.[8] Advances in monitoring technology and pain management techniques create opportunities for anesthesiologists in which to not only participate, but also manage many aspects of postoperative care in the home. Although these changes have been beneficial to many patients with improved outcomes and reduced costs, for some families the transition to short hospital lengths of stay has created significant clinical and social problems. Anesthesiologists must have an understanding of patients perioperative and postoperative support needs and should be actively engaged in determining the most appropriate setting for a procedure and how to manage the transitions of care.[9]

In addition to the changes taking place for surgical patients, anesthesia care is also shifting outside the operating room as a result of the advances in minimally invasive techniques provided by cardiologists, radiologists, endoscopists, and pain medicine specialists (see Chapters 51, 55, 57, and 73). As the volume of these services increases, anesthesiologists may be asked to provide care in procedural areas that were not designed for delivery of anesthesia services, and often not properly equipped to support patient and provider needs. The locations are frequently remote from the operating suite and may lack the usual support available for the care of patients with complex cases and the management of crises. Anesthesiologists therefore must participate in planning for these services and provide leadership in defining and maintaining the same standards of operating room practice to other areas of the hospital.[10,11]

Another example of the advances in clinical care and implications is the remarkable increase in referrals for colonoscopy for colon cancer screening.[12] Although the sedation provider for colonoscopy widely varies internationally and regionally within the United States, anesthesiologists are now more commonly participating in the care of these patients, in part due to medical needs related to comorbidities, but also because of documented complications associated with the use of sedation that have resulted in airway compromise or respiratory failure. These complications have caused providers and payers to reevaluate patient needs, the appropriate training of practitioners delivering procedural sedation, and when to optimize care by having an anesthesia practitioner monitor the patient and administer sedation. American[11,13] and international[14,15] sedation guidelines recognize that for many patients, nonanesthesiologist physicians and independent or semi-independent nonmedical practitioners can provide deep sedation for endoscopy; however, all guidelines emphasize that anesthesiologists should be involved in the care of high-risk patients or those with significant comorbidities.

CHANGES IN THE ANESTHESIA WORKFORCE

As a result of advances in perioperative care and the many other changes that impact the need for anesthesia practitioners, global and regional workforce shortages have been identified in recent years and are expected to increase (see Chapter 2). There are a number of reasons for these deficits including an insufficient number of medical graduates (in some places exacerbated by outward migration and an aging workforce), duty hour restrictions for practicing physicians (due to regulation of work hours, changing lifestyle preferences, and desire for better work-life balance), and increased demand for medical services (due to population growth and on a per capita basis). In addition to the impact of these societal changes, demand for physician care in the United States has increased in part due to the Patient Protection and Affordable Care Act (Affordable Care Act) with more patients having medical insurance and seeking care. To respond to the shortages, many countries within the Organisation for Economic Co-operation and Development (there are 36 member countries, including the United States) have increased medical school admissions in recent years.[16] Unfortunately, even this increase in number of trainees is insufficient to meet future needs. In 2017, the United States produced 7.55 medical graduates per 100,000 population, well below average (12 per 100,000 inhabitants). The Association of American Medical Colleges (AAMC) projects a shortage of up to 121,000 physicians by 2030.[14] At the same time, despite the increases in medical student enrollment, in the United States, most residency positions are funded by the Medicare program. As the medical school intakes have increased, this federal funding for residency positions (including anesthesiology) has not kept pace resulting in a bottleneck in the training pipeline. Along with reconsidering the cap on federally-funded positions, the AAMC has proposed alternative ways to leverage the skills and experience of physicians to advance care with improved use of technology and more interdisciplinary, team-based care as potential solutions.

Team-based care (anesthesia care team model) is already common in anesthesia practice, particularly in the United States. In the United States, the number of physician and nonphysician anesthesia providers are approaching parity, with the number of nurse anesthetists and anesthesia assistants increasing more rapidly than the number of physician anesthesiologists. In 2017, the American Society of Anesthesiologists (ASA) released a statement on the anesthesia care team that enunciated its vision for physician-led teams where anesthesiologists have a particular role in governance, planning, and oversight of anesthesia care, advanced airway management, and resuscitation.[17] This oversight includes defining and monitoring sedation provided in non-operating room locations and other requirements for the credentialing of providers to optimize care of the patient who requires deep sedation. Similar team-based approaches to care associated with physician supervision are commonplace or emerging in other countries around the world.

The number of women in medical schools has increased to over 50% of the student cohort in many countries. At the same time, until recently, United States anesthesiology training programs have recruited a smaller proportion of women (37%). In academic departments, few women have reached the rank of professor, or become department chairs, or been elected to leadership positions in representative anesthesia organizations.[18] Programs to improve recruitment and advancement of women in academic medicine and anesthesiology have gained traction in the last decade (e.g., Athena Scientific Women's Academic Network[19]). In addition, all academic programs are paying more attention to diversity in the workforce, particularly among women and underrepresented minorities. With the increased understanding of the inequities, programs can be developed to more effectively address the disparities and broaden the diversity of the anesthesia workforce. It is essential that the anesthesia workforce reflect the diversity of the patient population that is served.

INCREASING COSTS OF CARE

The costs of health care continue to grow internationally, with health care consuming 8% of gross domestic product (GDP) on average in most countries, whereas in the United States the costs are as high as 18% of GDP.[20] Unfortunately the increased healthcare expenditures have not translated into improved health outcomes, particularly for Americans. Despite the Affordable Care Act, the United States continues to have a large uninsured or underinsured population, lapses in quality and safety of care inside and outside the hospital, and high rates of drug abuse, violence, and use of firearms.[21] The National Academy of Medicine concluded that healthcare funding in the United States needs to "reorient competition in the healthcare system around the value of services provided rather than the volume of services provided." This transition from volume to value is creating many new challenges and opportunities for anesthesiologists. As the health system adopts practices that provide documented improved outcomes at reduced costs, anesthesiologists must both understand the implications of these changes in clinical practices and also take a leadership role in identifying opportunities to reengineer care if the specialty is to retain its leadership role in quality and safety (see Chapter 3).

Payment for physician services is being modified to better align health systems, providers, and payers with respect to delivery of high-quality, patient-centered care. Compensation for clinical care continues to have a fee-for-service component, particularly in the United States; however, more compensation is becoming incentive-based to encourage changes in practice that improve efficiency and effectiveness. In contrast to fee-for-service models (which reward inputs), pay-for-performance models reward medical care that is consistent with published evidence and that improves the processes of care (e.g., timely administration of perioperative antibiotics), output (e.g., meeting targets for urgent surgery), or outcome (e.g., fewer central-line associated blood stream infections) measures. In the United States, recent pay-for-performance programs have included the Premier Hospital Quality Incentive Demonstration program of the Centers for Medicare and Medicaid Services (2003–2009) and the national Hospital Value-Based Purchasing Program, adopted after the passage of the Affordable Care Act (2011). This initial attempt to modify anesthesia practice has had limited impact on outcomes, possibly because financial incentives are too small, payment is delayed, and/or the costs associated with implementing the programs is greater.[22] Nonetheless, incentive-based pay-for-performance programs (which are widespread in other nations with high-cost healthcare systems) will continue to expand.[23]

In addition to paying for high-quality performance, in the United States and other high-income nations there has been increasing emphasis on not paying for poor outcomes of errors in care. For example, some payers withhold payment for "never" events (e.g., wrong-sided surgery, pressure ulcers, retained foreign objects, mismatched blood transfusion) unless they are present on admission to the hospital. This approach may be expanded to withhold payment associated with treatment of preventable complications. A number of anesthesia-specific activities have been identified that impact outcomes and, if these are not provided, the consequence could be either no payment or penalties. For example, monitoring and maintaining body temperature during surgery as promoted by the Surgical Care Improvement Project is but one example of an anesthesia metric that affects outcomes and costs of care.[24] At the same time, identification of some of the interventions or monitoring techniques that impact outcome is challenging. As a result, it is critically important for anesthesiologists to continue to evaluate practices and do additional research to both optimize care and reduce costs.

Other changes in payment for clinical care have and will continue to have significant impact on compensation for anesthesia services. Some payers are providing "bundled" payments to compensate providers for episodes of care. This approach to payment is an integral part of the reforms introduced under the Affordable Care Act, although some of the incentives may be redefined by subsequent legislation. The Bundled Payments for Care Improvement initiative introduced by the Centers for Medicare and Medicaid Services tested the ability of bundling payments as a method for improving quality and lowering costs. The program has been most successful for selected clinical services such as total joint arthroplasty for which participation by anesthesiologists through the continuum of care can be most significant.[25] The ASA has proposed the Perioperative Surgical Home as an anesthesiologist-managed structure to coordinate perioperative team-based care. This model of coordinated care throughout the perioperative period should be amenable to bundled payments or other new approaches to compensating providers.[26]

INCREASING FOCUS ON SAFETY AND QUALITY

Anesthesiology was among the first medical specialties to focus on improving patient safety.[27] A number of initiatives have had major impact on outcomes of care, including improved monitoring techniques, airway management options, and new improved drugs. Anesthesiologists have been actively assessing clinical care through the use of incident reporting systems, morbidity and mortality conferences, and "near-miss" reports. Incident reporting, which was initiated in the United States more than 50 years ago, has documented a decline in anesthesia-related mortality to less than 1 per 1 million population.[28] In recent years national incident reporting programs have been initiated by the Anesthesia Quality Institute (Anesthesia Incident Reporting System[29]) and the Society of Pediatric Anesthesia (Wake Up Safe[30]). In addition to helping identify areas in which to improve clinical care, these programs provide legal protection to practitioners under the Patient Safety and Quality Improvement Act (2005). A number of programs have developed based on the experiences identified through these reporting mechanisms. Recognition of the human factors associated with adverse events has spawned a national and international movement directed at improving situational awareness and team functioning through simulation training (see Chapter 6). More recently programs to encourage healthcare providers and consumers to speak up about traditional patient safety concerns (e.g., commencing a wrong-side procedure) and unsafe professional behaviors (e.g., bullying and sexual harassment) have been integrated into workplaces nationwide and internationally.[31]

Anesthesiologists also led the way in the development of practice standards and checklists to improve clinical care. In some cases, the implementation of checklists has become a requirement for accreditation. In the last decade anesthesiologists were pivotal in the development, implementation, and evaluation of the World Health Organization's Surgical Safety Checklist.[32] Although the uptake of the Checklist has been patchy and its effect on outcomes has been inconsistent, the Checklist is widely implemented in the United States and other countries (see Chapter 2) in the belief that it will enable effective communication and a culture of safety.[33]

As anesthesia has become more and more safe, our attention has increasingly been focused on quality improvement, a process designed to improve patient experience and outcomes through systematic change and evaluation. In the United States, the Anesthesia Quality Institute established the National Anesthesia Clinical Outcomes Registry to enable systematic collection of quality information for use in quality improvement processes both nationally and locally.[34] Recently greater emphasis has been placed on longer-term and patient-centered or patient-reported outcomes. Many of these outcome measures have been incorporated into quality improvement programs and publicly reported metrics.[35] Anesthesiologists have identified the importance of assessing outcomes beyond the immediate perioperative period. As anesthesiologists assume a greater role in overall periprocedural care and outcomes, they will undoubtedly continue to advance the safety and quality agenda in large part due to their longstanding history in safety and quality as well as their training and pivotal role in perioperative care.

NEW OPPORTUNITIES AND CHALLENGES IN RESEARCH

Academic anesthesia departments are committed to advancing the scientific underpinning of anesthesiology. Basic, translational, clinical, and implementation research is vital to the continuous improvement in patient and health service outcomes (see Chapter 89). Fortunately, overall funding for biomedical and health services research in the United States more than doubled between 1994 and 2012. Although overall research funding has increased, since 2004 the overall growth of NIH funding for medical research has declined by 1.8%.[36] Private sources of funding have been important to supplement government-sponsored research support. Industry support is valuable and has been critical to the research agenda for academic departments. It also creates both real and perceived conflicts of interest that can be difficult to manage. Over the past decade, there has been a decline in early-stage research in favor of device development and clinical trials, poor mapping of research effort to the global burden of disease, and limited funding for critically important health services research.[36]

The implications of these changes in research support on anesthesia are significant. Academic anesthesia departments in the United States, as well as many other countries, continue to compete for government funding. Most benchmarks suggest that the specialty of anesthesiology in the United States fares poorly in National Institutes of Health funding when compared with other disciplines.[37] As a result, anesthesia departments, particularly in the United States have had to identify other funding sources, including foundations, industry, and philanthropy, particularly for early-career investigators.[38] For example the Foundation for Anesthesia Education and Research (FAER) has awarded more than $40 million in grants since 1986 and has demonstrated the leverage that these grants provide in achieving federal funding ($17 in funding for every $1 investment). Similar programs are funded by the International Anesthesia Research Society and by other anesthesiology organizations and foundations worldwide. At the same time, and in many respects related to the funding challenges and competing clinical needs, research support and peer-reviewed publications, which have increased in other countries, have not kept pace in the United States. As a result, an increasing number of publications in peer-reviewed journals are from authors outside the United States.

Other factors have impact on what resources are available for research. The clinical demands put on the faculty in academic departments make it difficult for clinician scientists to pursue research activities. Associated with the increasing clinical volume, supervised residents cannot provide all of the clinical care without compromising their educational experiences and fulfilling duty hour and other requirements. As a result, the faculty members are delivering a larger percentage of care on their own. At the same time, the complexity of some of the basic and translational research requires significant dedicated time and skills that are difficult to maintain when the investigator is also encumbered with a high clinical demand. Historically, clinically generated income was used to support research in general and young investigators in particular. As labor and other costs increase (including those associated with quality of care initiatives, clinical and research compliance, and other activities), fewer funds are available to support research. As a result of the high cost of developing new drugs with insufficient incentives for the pharmaceutical industry to develop new anesthetic agents, there is a reduced pipeline of anesthesia drugs.[39]

Despite these challenges, basic science, as well as clinical and translational research, is being performed by anesthesiologists and advances in the specialty are taking place. New models for research have contributed to advances in our understanding of basic concepts of anesthesia care as well as clinical advances. As is true for clinical care, collaboration has always been vital in biomedical research. In recent years anesthesiology research has increasingly been conducted by multiprofessional, multidisciplinary teams including biostatisticians, health informaticians, and health economists. Translation from discovery to practice has been facilitated by partnerships among basic scientists, clinical scientists, and implementation scientists.[40] In addition to collaborations among colleagues within one institution, increasingly clinical trials are being conducted by large, multicenter networks because of the recognition that single-center studies take too long and cannot recruit enough patients to answer the really important questions in anesthesiology.[41-44] Research based on electronic medical records and databases also requires collaboration between institutions, clinicians, and database experts (see later).

One of the primary motivators to support the research agenda for anesthesiology is the need to define reliable and peer-reviewed data upon which to advance the specialty. Although the volume of anesthesiology information and its ease of access have increased exponentially in the last decade, particularly through social media, anesthesiologists are progressively challenged to find reliable information to guide their practice. In addition to the difficulty of assessing the quality of some of the information posted on various web sites, anesthesiology has also been plagued by high-profile cases of research misconduct, including fabrication, falsification, and misleading reporting of research findings.[45] This has damaged the reputation of anesthesiology research and, as a result of unreliable data upon which to make clinical decisions, put patients at risk. Each anesthesiologist must be diligent in selecting a source of information that takes into consideration the standards of peer review of the material and the financial relationships between the authors and publishers.[46]

INCREASING AVAILABILITY OF DATA

One of the areas of opportunity with respect to better understanding our clinical practices and defining ways to improve care is the increasing amount of data that can inform us. The last decade has seen unprecedented growth in the volume and availability of healthcare data. Electronic health record (EHR) systems (see Chapter 4) facilitate complete data capture and integration from multiple sources, including surgical equipment, anesthesia delivery systems, and physiologic monitors. The EHR has greatly facilitated documentation of individual patient care and provided aggregate data for healthcare services and populations. Other sources of routinely-collected data include health service billing systems, government and insurance databases, disease registries, and public health reporting. In addition, data specifically collected for research and quality improvement is increasingly shared, including research databases and biobanks (including genetic databanks). Meta-data related to the use of electronic resources and social media is also available for interrogation. These data require new management and analysis techniques that are beyond the scope of the practicing anesthesiologist or researcher (see Chapter 4). Truly “big” data includes terabytes of information, is generated and analyzed at high speed, and includes data in a wide variety of formats and from a wide variety of sources.[47]

These large data sets are increasingly being used to answer important research questions, to develop evidence-based clinical guidelines, and to assess the safety and quality of anesthesia and perioperative care, within and across different clinical environments and regions. Although technologic resources are not replacing randomized clinical trials, the information gleaned from large databases can be used to address important questions about how to most effectively deliver cost-effective care. At the same time, it is important to acknowledge the limitations of large databases, which may have missing critical elements of care or outcomes, could misclassify data, or in some cases, lack verification.[48]

Conclusions

The scope of modern anesthetic practice is continually changing and expanding. The forces for change include changes in our patient population, locations of care, workforce, costs, quality and safety initiatives, research, and the availability of data. This chapter emphasizes the implications for these forces on the specialty as well as the influence they have on the delivery of health care in general. The changes occurring in health care in the 21st century obviously have implications for the role of anesthesiology in both the practice and delivery of medicine overall, and provide exciting opportunities for the next generation of practitioners and leaders in our specialty.

Acknowledgment

The editors and publisher recognize the contributions of Ronald D. Miller, who was a contributing author to this topic in previous editions of this work. It has served as the foundation for the current chapter.

Global Health Competencies
Conclusions

KEY POINTS

- More than 5 of the world's 7 billion people lack access to safe anesthesia and surgical services. Surgical disease accounts for 30% of global disease burden, yet less than 1% of development assistance for health supports delivery of anesthesia and surgical care. Lack of access to safe, timely, and affordable anesthesia and surgery kills more than 4 times as many as acquired immunodeficiency syndrome (AIDS), tuberculosis (TB), and malaria combined.
- Lack of access to safe anesthesia and surgical services are among the most neglected crises in global health. Anesthesia-related mortality in some low-income countries (LICs) is reported in the 1:100s and is mostly avoidable. The burden of surgical disease is growing and disproportionately affects low- and middle-income countries.
- Pain is one of the top causes of morbidity worldwide, and inadequate access to analgesia is among the most inequitable global public health crises the world faces today. Five and a half billion people have limited or no access to narcotic medications for analgesia. Six high-income countries (HICs) account for 80% of the world's opioid consumption. Key drug control policies, organizations, and politics continue to influence issues of access and abuse, with disproportionately negative impacts for underserved populations.
- Critical shortages and the inequitable distribution of anesthesia providers are significant barriers to increasing access to safe anesthesia and surgical care. The density of surgery, anesthesia, and obstetric providers is 0.7 per 100,000 population for LICs as compared with 57 per 100,000 population for HICs.

KEY POINTS—cont'd

- Modern anesthesia workforce training and practice models vary widely from country to country. Innovative workforce solutions are needed to increase provider numbers while simultaneously ensuring quality and promoting access for underserved populations.
- Anesthesia, analgesia, and surgical services are feasible in resource-constrained settings and are as cost-effective as many other public health interventions (e.g., vaccinations).
- Issues of access, safety, and resource utilization are relevant to all anesthesia providers. Equipping anesthesia providers with knowledge and skills needed to address global challenges in anesthesia will become increasingly important in order to expand access to safe and affordable anesthesia care worldwide.
- Health care providers from multiple disciplines (nursing, surgery, obstetrics, anesthesia, and many more) are needed to effectively provide surgical and perioperative care. Anesthesiologists routinely work across the perioperative disciplines and can play a significant role to improve cohesive advocacy efforts and lead progress in global health equity for surgical disease and analgesia.
- The global anesthesia community is lagging behind other health disciplines in addressing global health challenges and must rapidly expand investment in initiatives to help characterize (research), address (implementation and policy), and support (financing) global anesthesia challenges.
- Developing infrastructure, expanding workforce, improving data to drive policy, providing financial risk protection mechanisms for surgical patients, improving referral and prehospital systems, and providing essential medicines are actions the global anesthesia community must prioritize. The need to act promptly is immense and must be balanced but not overshadowed by research agendas.

Introduction

There have been considerable efforts in recent years to define a global "standard" or "optimal" practice of anesthesia.[1-4] These debates, investigations, and innovations have most often been framed in the context of maximizing patient safety. More recently the focus of these efforts has expanded to also incorporate the important goals of maximizing not only safety, but also accessibility and affordability of anesthesia services.[5]

With scientific advancement and economic development, anesthesia—like much of medicine—has changed dramatically since the first public display of ether anesthesia in October of 1846. However, over the past 150-plus years, advances in anesthesia have been neither uniform nor universal, resulting in vastly heterogeneous anesthesia practice models and massive inequities in access to safe anesthesia care worldwide. The majority of the world's population does not have access to safe, affordable surgical, anesthesia, or pain services, and relatively few resources are being invested by governments, donors, or the global anesthesia community to address this crisis.

In this chapter we build off the work of Dr. Miller and colleagues' to explore not only the evolution and diversity of anesthesia practice models from around the world, but also challenges facing the global anesthesia community. A better understanding of the evolution of modern anesthesia care models, as well as the challenges they face and have overcome, is a key step to improving access and patient safety worldwide.

The first section of this chapter describes the scope and magnitude of the ongoing global surgical, anesthesia, and pain crises. This section also explores reasons why these crises have been relatively neglected by the global public health community, and reviews potential areas for intervention, advocacy, and change.

TABLE 2.1 World Bank Income Classifications by Gross National Income per Capita

	GNI per Capita (US $)
Low income	<1,005
Lower-middle income	1,006-3,955
Upper-middle income	3,956-12,235
High income	>12,235

GNI, Gross national income.

The second section of this chapter presents examples of different anesthesia care models from around the world, including select historical milestones and snapshots of current challenges from regional and country-level perspectives.

The final section of this chapter provides a primer on essential clinical and nonclinical knowledge relevant for anesthesia practice in resource-constrained settings. The chapter concludes by discussing the role of anesthesia providers beyond the confines of the operating room or hospital setting, who increasingly will be called upon for solutions that increase access to safe anesthesia, surgery, and analgesia in the global context.

Section 1: Anesthesia and "Global Health"

The terms anesthesia and global health, when used together, often invoke thoughts of providers from high-income countries (HICs) providing clinical care in low- and middle-income countries (LMICs) as part of humanitarian outreach or "mission trips" (Table 2.1). Although such initiatives comprise a substantial proportion of efforts that

TABLE 2.2 Definitions of Global Health and Global Surgery

	Global Health*	Global Surgery†
Approach	Field of study, research, practice and advocacy. Emphasizes global perspective and a scientific approach to health promotion and disease prevention, including broad determinants of health.	Area for study, research, practice, and advocacy that places priority on improving health outcomes and achieving health equity for all people worldwide who are affected by surgical conditions or have a need for surgical care.
Geography	Focuses on issues that directly or indirectly affect health but that can transcend national boundaries.	Global surgery emphasizes supraterritorial and transnational issues, determinants, and solutions.
Level of cooperation	Development and implementation of solutions often require global cooperation.	Recognizes that the determinants of inadequate or inequitable surgical care are often the result of common and interdependent global structures and processes, and require global cooperation for global solutions.
Individuals or populations	Embraces both prevention in populations and clinical care of individuals.	Encompasses surgical care for underserved populations in all countries with special emphasis on those affected by conflict, displacement, and disaster.
Access to health	Health equity among nations and for all people is a major objective.	Equitable access to safe and affordable anesthesia, analgesia, and surgical care is a major objective.
Range of disciplines	Highly interdisciplinary and multidisciplinary within and beyond health sciences.	Incorporates all surgical specialties including obstetric and gynecological surgery, anesthesia, perioperative care, aspects of emergency medicine, rehabilitation, and palliative care, and nursing and the allied health professions involved in the care of the surgical patient. Engages non-clinical stakeholders including health economists, governments, and policymakers.

*Modified from Koplan JP, Bond TC, Merson MH, et al. Towards a common definition of global health. *Lancet*. 2009;(9679);1993–1995; Fried LP, Bentley ME, Buekens P, et al. Global health is public health. *Lancet*. 2010;375(9714):535–537.

†Modified from Dare AJ, Grimes CE, Gillies R, et al. Global surgery: defining an emerging global heath field. *Lancet*. 2014;384(9961):2245–2247.

aim to increase access to surgical and anesthesia services in resource-constrained settings, they represent only a fraction of the ever-expanding role of the anesthesia community in global health.

In this chapter, the term "global health" refers to a multidisciplinary field of study, research, practice, and advocacy that develops and implements solutions to promote health equity. Global health transcends national boundaries, requires global cooperation, and utilizes both population-level (e.g., injury prevention) and individual-level (e.g., clinical care) strategies (Table 2.2). Although some debate exists over the optimal definition of global health and its distinction, or lack thereof, from public health, it is worth highlighting that global health is not synonymous with international aid (i.e., going abroad from one's own country) or the transfer of technologies or interventions from HICs to LMICs.[6,7] Global health encompasses much more, including local providers working in the local environment (whether that is a low-, middle-, or high-income setting), and increasing emphasis on health equity.[8]

Global health has received unprecedented levels of interest in recent decades, expanding from its infectious disease origins to now incorporate a wider range of diseases, including the social and environmental factors affecting health.[9,10] Despite this expanded scope, surgery and anesthesia have remained relatively forgotten by the global health community.

In June of 1980, then Director-General of the World Health Organization (WHO), Dr. Halfdan Mahler, gave a presentation to the International College of Surgeons in Mexico City entitled "Surgery and Health for All." In this speech, Dr. Mahler stated that "*Surgery clearly has an important role to play in primary health care and in the services supporting it. Yet, the vast majority of the world's population has no access whatsoever to skilled surgical care, and little is being done to find a solution. I beg of you to give serious consideration to this most serious manifestation of social inequity in health care.*"[11]

Despite recognition of the global anesthesia and surgical crises several decades ago, it has been only recently that the global health community has begun to take notice and action.[12–17] In 2004, the WHO created the Emergency and Essential Surgical Care Program (EESC) and in 2005, the WHO Global Initiative for Emergency and Essential Surgical Care (GIEESC) was formed to convene multidisciplinary stakeholders interested in surgical disease. In 2007, the Bellagio Essential Surgery Group and Burden of Surgical Disease Working Group (later renamed the Alliance for Surgery and Anesthesia Presence [ASAP]) formed as two of the earliest concerted efforts to raise international awareness for surgical disease by advocating for the integration of surgery into health systems and the promotion of research and collaboration across disciplines.[18] These efforts followed in the wake of a seminal chapter on surgery in the Second Edition of the Disease Control Priorities in Developing Countries (DCP2) book in 2006.[19] In 2008, the WHO launched the Safe Surgery Saves Lives initiative along with the WHO Safe Surgery Checklist.[20,21] Also in 2008 multiple leaders in global health highlighted surgery as the "neglected stepchild" and as the "other neglected disease" in global health, drawing comparison with the then emerging term, "neglected tropical diseases."[22,23]

Despite these pleas and consistent, albeit limited, data demonstrating the massive scale of the surgical disease crisis, it was not until 2014–15 that greater attention began to be realized. In 2014, the Amsterdam Declaration on Essential Surgical Care was created, and in 2015, the 68th World Health Assembly (WHA) unanimously passed resolution 68.15 (WHA68.15) to strengthen emergency and essential

BOX 2.1 Key Messages From the Disease Control Priorities 3rd Edition

- Provision of essential surgical procedures would avert an estimated 1.5 million deaths a year, or 6%-7% of all avertable deaths in low- and middle-income countries (LMICs).
- Essential surgical procedures rank among the most cost-effective of all health interventions. The surgical platform of first-level hospitals delivers 28 of the 44 essential procedures, making investment in this platform also highly cost-effective.
- Measures to expand access to surgery, such as task-sharing, have been shown to be safe and effective while countries make long-term investments in building surgical and anesthesia workforces.
- Because emergency procedures constitute 23 of the 28 procedures provided at first-level hospitals, such facilities must be widely geographically available.
- Substantial disparities remain in the safety of surgical care, driven by high perioperative mortality rates and anesthesia-related deaths in LMICs. Feasible measures, such as the World Health Organization's (WHO's) Surgical Safety Checklist,[27a] have led to improvements in safety and quality.
- The large burden of surgical conditions, the cost-effectiveness of essential surgery, and the strong public demand for surgical services suggest that universal coverage of essential surgery (UCES) should be financed early on the path to universal health coverage.
- We point to estimates that full coverage of the component of UCES applicable to first-level hospitals would require slightly more than $3 billion annually of additional spending and yield a benefit to cost ratio of better than 10:1. It would efficiently and equitably provide health benefits and financial protection, and it would contribute to stronger health systems.

From Jemison DT, Alwan A, Mock CN, et al: Universal health coverage and intersectoral action for health: key messages from Disease Control Priorities, 3rd edition. The Lancet 391, Issue 10125, 2018:1108–1120.

BOX 2.2 Key Messages From The Lancet Commission on Global Surgery

- 5 billion people do not have access to safe, affordable surgical and anesthesia care when needed. Access is worst in low-income and lower-middle-income countries (LMICs), where 9 of 10 people cannot access basic surgical care. 143 Million additional surgical procedures are needed in LMICs each year to save lives and prevent disability. Of the 313 million procedures undertaken worldwide each year, only 6% occur in the poorest countries, where over a third of the world's population lives. Low operative volumes are associated with high case-fatality rates from common, treatable surgical conditions. Unmet need is greatest in eastern, western, and central sub-Saharan Africa, and South Asia.
- 33 Million individuals face catastrophic health expenditure due to payment for surgery and anesthesia care each year. An additional 48 million cases of catastrophic expenditure are attributable to the nonmedical costs of accessing surgical care. A quarter of people who have a surgical procedure will incur financial catastrophe as a result of seeking care. The burden of catastrophic expenditure for surgery is highest in low-income and lower-middle-income countries and, within any country, lands most heavily on poor people.
- Investing in surgical services in LMICs is affordable, saves lives, and promotes economic growth. To meet present and projected population demands, urgent investment in human and physical resources for surgical and anesthesia care is needed. If LMICs were to scale-up surgical services at rates achieved by the present best-performing LMICs, two thirds of countries would be able to reach a minimum operative volume of 5000 surgical procedures per 100,000 population by 2030. Without urgent and accelerated investment in surgical scale-up, LMICs will continue to have losses in economic productivity, estimated cumulatively at US$12.3 trillion (2010 US$, purchasing power parity) between 2015 and 2030.
- Surgery is an "indivisible, indispensable part of health care."[1] Surgical and anesthesia care should be an integral component of a national health system in countries at all levels of development. Surgical services are a prerequisite for the full attainment of local and global health goals in areas as diverse as cancer, injury, cardiovascular disease, infection, and reproductive, maternal, neonatal, and child health. Universal health coverage and the health aspirations set out in the post-2015 Sustainable Development Goals will be impossible to achieve without ensuring that surgical and anesthesia care is available, accessible, safe, timely, and affordable.

Mock CN, Donkor P, Gawande A, et al: Essential surgery: key messages from Disease Control Priorities, 3rd edition. The Lancet 385, Issue 9983, 2015: 2209–2219.

surgical and anesthesia care as a component of universal health coverage.[24,25] Also in 2015, publication of DCP3 and the Lancet Commission on Global Surgery (LCOGS) "Global Surgery 2030" report significantly expanded the body of data characterizing the global surgical and anesthesia crises, and also outlined strategies for addressing some of these challenges (Boxes 2.1and 2.2).[5,26] During the LCOGS development, Jim Kim, President of the World Bank, echoed the words of Dr. Mahler from 35 years earlier by stating, "…surgery is an indivisible, indispensable part of health care and of progress towards universal health coverage."[27]

These events provided a much needed boost to efforts aimed at improving the accessibility, affordability, and safety of surgical, obstetric, and anesthesia care worldwide. They also helped provide a framework for including surgery and anesthesia as global health priorities by linking surgery and anesthesia care to universal health coverage. Surgery and anesthesia were not included in previous priority-setting efforts, in part, because it was not clear how to incorporate them. Limited data about the scale of the crises, as well as misperceptions around complexity and cost-effectiveness (as discussed in the next section) resulted in surgery and anesthesia care being peripheral to global health priority-setting efforts like the Millennium Development Goals (MDGs). Although surgery and anesthesia are not explicitly a focus of more recent global health priority initiatives like the Global Health 2035 report and the United Nations (UN) Sustainable Development Goals (SDGs), these reports emphasize noncommunicable diseases, injuries, healthcare workforce expansion, and universal health coverage, which incontrovertibly depend on surgery and anesthesia.[28,29]

Milestones like LCOGS, the WHA resolution 68.15, and the Lancet Commission on Palliative Care and Pain Relief have helped call attention to the global anesthesia, analgesia, and surgery crises at hand.[30] Entities like the World Federation of Societies of Anaesthesiologists (WFSA), Association of Anesthetists of Great Britain and Ireland (AAGBI), Canadian Anesthesiologists' Society International Education Foundation (CASIEF), and Lifebox are among the increasing number of anesthesia organizations working on system-level changes, research, and large-scale education initiatives in LMICs. Many national anesthesia societies, such as the United Kingdom's Royal College of Anaesthetists (RCoA), the Royal College of Anesthesiologists of Thailand, and the Chilean Society of Anesthesiologists are also actively engaged in such activities. The number of these global anesthesia efforts is unprecedented, but still nascent and evolving.

If surgery is described as the neglected step-child of global health, then anesthesia is the forgotten relative. Despite significant interdependence, surgery, anesthesia, and obstetrics have yet to harmonize global health efforts and maximize impact. Global health efforts involving either surgery or anesthesia have become known collectively as "global surgery" (see Table 2.2). In 2014, "global surgery" was defined "…as an area for study, research, practice, and advocacy that places priority on improving health outcomes and achieving health equity for all people worldwide who are affected by surgical conditions or have a need for surgical care. Global surgery incorporates all surgical specialties, including obstetric and gynecologic surgery; anesthesia; perioperative care; aspects of emergency medicine; rehabilitation; palliative care; and nursing and the allied health professions involved in the care of the surgical patient. It encompasses surgical care for underserved populations in all countries and for populations affected by conflict, displacement, and disaster, and promotes access to safe, quality care. Global surgery emphasizes supraterritorial and transnational issues, determinants, and solutions, recognizing that the determinants of inadequate or inequitable surgical care are often the result of common and interdependent global structures and processes, even though they are predominantly experienced within individual countries and communities.[31]" This definition was abbreviated to state "global surgery is an area of study, research, practice, and advocacy that seeks to improve health outcomes and achieve health equity for all people who require surgical care, with a special emphasis on underserved populations and populations in crisis. It uses collaborative, cross-sectoral, and transnational approaches and is a synthesis of population-based strategies with individual surgical care." Although anesthesia is not directly mentioned in this definition, "global surgery" has become a rallying point for anesthesia global health efforts.

SCOPE AND SCALE OF THE GLOBAL ANESTHESIA, SURGERY, AND PAIN CRISES

Global Burden of Surgical Disease

Nearly 30% of global morbidity and mortality is surgically treatable, with tens of millions of lives lost each year due to surgical conditions.[5] This burden of surgical disease predominantly affects LMICs and kills 4 times more people than human immunodeficiency virus (HIV), TB, and malaria combined (Fig. 2.1).[32] In addition to negative impacts on health and well-being, there is also significant economic burden associated with surgical morbidity and mortality. By 2030, morbidity and mortality from surgical conditions could reduce annual gross domestic product (GDP) growth by an estimated 2% in LMICs. In the past, similar calculations were used to successfully generate global investment in malaria, but had estimated much lower (1.3%) decreases in GDP due to malaria.[33] Without significant and immediate intervention, surgical disease will produce economic productivity losses of more than US$12 trillion for LMICs between 2015 and 2030. While it is generally agreed that surgical conditions account for a large proportion of global morbidity and mortality, precise data to support this have been lacking. This challenge has been attributed in part to a lack of resources being invested in such research and also to several inherent difficulties in quantifying surgical diseases.

The term "global burden of disease" (GBD) uses the disability-adjusted-life-year (DALY) as a unit to quantify premature death (years of life lost) and disability (years of life lived in a state of less than full health) (Fig. 2.2). The DALY was originally developed for the seminal GBD 1990 Study to quantify the burden of different diseases around the world and has since become commonly used in public health and health economics.[34,35] Because the DALY is routinely used to inform resource allocation, it has been utilized to describe surgical and pain disease burdens as well. The global health community has moved away from using terms such as third world, developed, or developing when describing countries' level of economic development. Leading causes of DALYs are often reported geographically by World Bank income level (see Table 2.1) or more recently by socio-demographic index (SDI) (Figs. 2.3 and 2.4). The SDI is a composite average of three indicators predictive of health outcomes: income per capita, average educational attainment (for population >15 years old), and total fertility rate.

The 2006 DCP2 publication was one of the first attempts to quantify surgical disease burden and did so by asking 18 surgeons for an educated guess, using convenience sampling and an online survey. Although the reported number

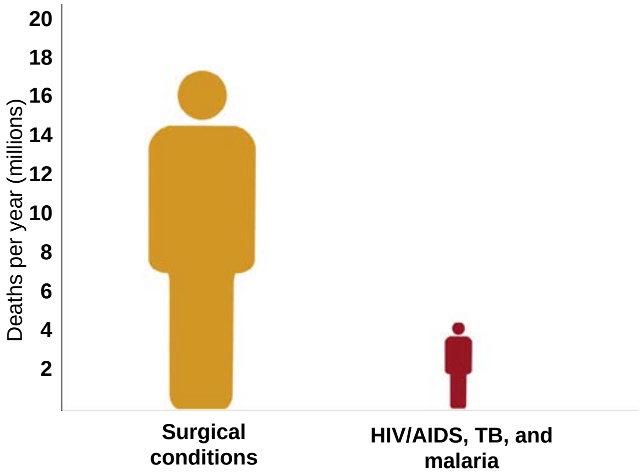

Fig. 2.1 Surgical conditions account for more annual deaths (16.9 million) than HIV/AIDS (1.03 million), TB (1.21 million), and malaria (0.72 million) combined. *AIDS*, Acquired immunodeficiency syndrome; *HIV*, human immune virus, *TB*, tuberculosis. (Data from Shrime MG, Bickler WS, Alkire BC, et al. Global burden of surgical disease: an estimation from the provider perspective. *Lancet Glob Health.* 2015;3:S8–S9; and GBD collaborators 2016. (11%) was eye-opening and widely quoted, it was likely a significant underestimation.

In 2015, the DCP3 provided another attempt to assess the public health impact of surgical care by estimating morbidity and mortality averted by scaling up basic surgical and anesthesia services in LMICs (i.e., surgical care for appendicitis, paralytic ileus, intestinal obstruction, hernias, gallbladder and bile duct disease, maternal hemorrhage, obstructed labor, abortion and neonatal encephalopathy, trauma resuscitation, surgical airway, peripheral venous access, suturing, laceration and wound management, chest tube or needle decompression, fracture reduction, escharotomy, fasciotomy, skin grafting, and trauma-related laparotomy and amputation). They concluded that an estimated 1.4 million deaths and 77.2 million DALYs could be prevented each year by scaling up basic surgical and anesthesia services in LMICs.[26]

The LCOGS produced another attempt to estimate global morbidity and mortality from surgical disease by asking 173 surgeons, anesthesiologists, internists, nurses, and public health practitioners from around the world, “What proportion of patients with the following conditions would, in an ideal world, require a surgeon for management?” The result of this survey was 28% to 32% of overall GBD requires a surgeon for management. Based on these results, LCOGS estimated that 30% of GBD is surgically treatable with an estimated 17 million lives lost per year due to surgical conditions.[5]

These reports are consistent with the 1990 GBD Study data, which demonstrate that the morbidity and mortality associated with surgical diseases is significantly larger than that of HIV, TB, and malaria combined.[32] Unintentional injuries are the single largest contributor of DALYs worldwide. The majority of deaths that can be prevented with surgical care are due to injuries (77%), maternal-neonatal

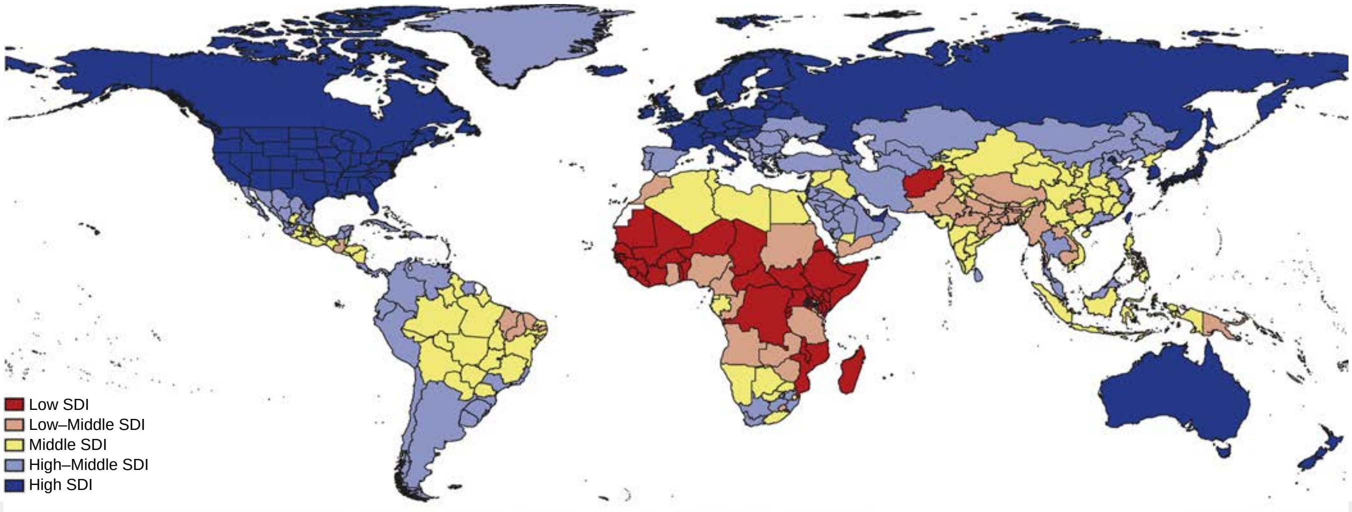

Fig. 2.3 Socio-demographic Index *(SDI)* is calculated for each geography as a function of lag-dependent income per capita, average educational attainment in the population older than age 15 years, and the total fertility rate. SDI units are interpretable; a zero represents the lowest level of income per capita and educational attainment and highest total fertility rate observed during 1980–2015, whereas a one represents the highest income per capita and educational attainment and lowest total fertility rate observed in the same period. Cutoffs on the SDI scale for the quintiles have been selected on the basis of examination of the entire distribution of geographies 1980–2015. *GBD,* Global Burden of Disease. (From GBD 2015 Mortality and Causes of Death Collaborators. conditions (14%), and digestive diseases (9%).[26] Global industrialization and an "epidemiological transition" (i.e., people living longer) in many LMICs have resulted in rising noncommunicable disease and injury burdens (most notably from road traffic crashes) that will likely contribute to increased global surgical disease burden in the coming years.

Each of the methods previously described to estimate surgical disease burden is imperfect. Challenges and limitations include complex methodologies (e.g., Institute for Health Metrics and Evaluation [IHME], GBD Studies), difficulty with measuring and defining surgical diseases (e.g., the same neoplasm in one person may be treated with surgery but in another person may be treated with chemotherapy), and challenges in assigning DALYs to diseases (i.e., disability weighting) and assigning DALYs averted to surgical procedures.[26] To overcome these shortcomings, additional metrics for global surgery and anesthesia have been proposed and include measuring disease prevalence, treatment backlogs for non fatal conditions, morbidity and mortality as a result of delays in care, social benefit, economic benefit, and value of a statistical life (rather than costs per DALY averted).[36]

One significant role for the academic anesthesia community in the global context is working to increase efforts that better quantify the growing surgical disease and pain burdens in order to facilitate appropriate resource allocation and subsequent evaluation of interventions.

Global Burden of Pain

As with surgical disease burden, there is general consensus on the staggering prevalence and incidence of pain worldwide though there are relatively limited data and significant challenges to quantifying pain burden in the global context. Pain is one of the most common reasons for seeking medical attention, is among the top five causes of DALYs worldwide, and directly accounts for four (low back pain, neck pain, musculoskeletal pain, migraine) of the top 10 causes of years lived with disability (YLDs).[32,37] These statistics do not even account for pain secondary to oncology, injury, or postoperative etiologies, which likely increase these numbers substantially. It is estimated that 10% to 25% of the world's population suffer from recurring and chronic pain, with increasing numbers caused by intentional physical harm such as war, violence, and torture.[38] Uncontrolled pain has many potential negative impacts on health, well-being, and economic productivity, including increased risk of myocardial infarction and chronic pain.

The 2017 Lancet Commission on Palliative Care and Pain Relief defined serious health-related suffering (SHS) as suffering associated with illness or injury that compromises physical, social, or emotional functioning, and cannot be relieved without medical intervention.[30] Approximately half of all deaths worldwide involve SHS and more than 80% of people who die with SHS are from LMICs. It is estimated that 2.5 million children die with SHS each year. Ninety-eight percent of these children live in LMICs, and more than 90% of these deaths are avoidable. Among the top 10 conditions associated with SHS are HIV, malignancy, and injury. Though not as obvious as injury or cancer, HIV/AIDS is a major source of pain and analgesia need.[39] Pain related to HIV is not routinely managed by anesthesiologists when compared to other more common pain etiologies, however, the relevance of HIV as a rallying point to advocate for greater access to analgesics in LMICs is discussed further in this chapter. In many countries, conditions such as diabetes, sickle cell, and leprosy are also responsible for significant pain burdens. With increasing longevity and industrialization, the disease burden for malignancy and injury are expected to increase significantly in LMICs. As providers with often the most experience administering analgesics, anesthesia providers play an expanded and critical role in pain management, especially in resource-constrained settings.

Disparities in Access, Affordability, and Safety

The exact level of disease burden attributable to surgical disease or pain is a focus of ongoing debate and research, yet it is generally accepted that the surgical, anesthesia, and pain crises are massive, largely avoidable, and disproportionately affect LMICs. Of the roughly 300,000 maternal deaths worldwide, 99% occur in low-resource settings (66% in sub-Saharan Africa) and the majority are preventable with relatively basic surgical, anesthesia, and perioperative care.[40] Approximately 70% of global cancer deaths occur in LMICs, with the majority requiring surgical, anesthesia, or analgesia services.[41] Scaling access to basic surgical and anesthesia services in LMICs could avert 77 million DALYs and 1.5 million deaths per year.[26] Injury represents the majority (77%) of this avoidable morbidity and mortality, followed by maternal and neonatal conditions (14%). Approximately 90% of deaths and DALYs that are lost due to road traffic accidents occur in LMICs.

Based solely on the inequitable distribution of operating theatres, more than two billion people have no access to surgical services.[42] When also accounting for timeliness, facility capacity, safety, and affordability, nearly 5 billion people—the majority of the world's population—lack access to surgical and anesthesia care. The Global Initiative for Children's Surgery (GICS) estimates that 1.7 billion children lack access to surgical care.[42a] It is estimated that approximately 143 million additional surgeries are required each year.[5] Of the 234 million major surgical procedures performed annually, only 3% to 6% of them are estimated to occur in LIMCs.[5,43] Disparities in access disproportionally affect lower-income areas like sub-Saharan Africa or South Asia, where more than 95% of the population do not have access to surgical and anesthesia care. In some higher-income areas like North America and Europe, access varies considerably, but generally more than 95% of the population has access (Fig. 2.5).[44] Even in HIC like the United States, access to anesthesia, surgical, and analgesia care can be limited for rural and underserved populations.[45,46] It is estimated that universal access to "essential" surgical procedures (which include treatments for injury, obstetric complications, abdominal emergencies, cataracts, and congenital anomalies) would prevent approximately 1.5 million deaths per year or 6% to 7% of all preventable deaths in LMICs.[26]

Inadequate access to analgesia is among the most neglected and inequitable global public health challenges. The global burden of pain disproportionately affects the world's poor due to the high-burden conditions associated with pain (e.g., HIV, malignancy, and injury) in LMICs, and the general lack of access to analgesics. Although pain is the most common reason for seeking medical attention, and analgesia is considered a basic human right, gaps in access to analgesia are significant and among the most striking global health disparities worldwide.[47–49] Injury and malignancy, two conditions with significant analgesia needs, represent a significant proportion of surgical disease burden in LMICs, yet the vast majority of LMIC populations have limited or nonexistent access to opiate analgesia. Six HICs account for 80% of the world's opiate consumption, and countries that contain 17% of the world's population (Canada, United States, Western Europe, Australia, and New Zealand) are responsible for 92% of the world's opiate consumption (Figs. 2.6 and 2.7).[30,50-52] Pain and palliative care remain relatively neglected by the global health community and disproportionately affect vulnerable populations in LMICs.[30,53] In recent decades, access to opiates has improved in some LMICs, but not all (e.g., consumption in Africa and South Asia has declined).[52] Inequitable access to analgesia is not unique to LMICs and has been repeatedly described in many HICs, including the United States.[54-56] Reasons for the inequitable distribution of analgesia are discussed further in the next section of this chapter.

For the proportion of the world's population that has access to surgical and anesthesia care, they must confront significant disparities in safety. In the last half-century perioperative patient safety has improved by more than 10-fold, though the majority of the gains have been seen in HICs.[57] In the United States during the 21st century, anesthesia-related mortality decreased from 1:1560 around 1950 to less than 1:13,000, and is significantly better than this in healthy patients.[58,59] Worldwide, approximately 32 million people per year receive anesthesia without adequate monitoring, and more than 77,000 operating rooms (19%) worldwide lack pulse oximetry. In some regions, more than 70% of operating rooms lack pulse oximetry.[42] Data on surgical outcomes in LMICs remain limited but have expanded significantly in the early part of the 21st century. Reports of perioperative mortality rates (POMRs) from low-income countries (LICs) have varied widely in both methodology and results, ranging from 0.2% to 6% overall, with significantly higher mortality for emergent procedures (10% overall, 20% for typhoid intestinal perforations).[60–64] One international, prospective, observational cohort study of adults undergoing inpatient surgery in 247 hospitals from 25 African countries reported a 30-day in-hospital mortality rate (2.1%) that was twice the reported global average, despite a significantly younger and lower American Society of Anesthesiologists (ASA) physical classification patient population.[65]

In several African countries, anesthesia-related mortality has been reported to be in the 1:100s (Malawi 1:504; Zimbabwe 1:482; Nigeria 1:387 for C-sections; Togo 1:133 to 1:250).[66–69] In one report of 24-hour surgical outcomes in Togo, 30 deaths occurred (total cases 1464), 22 were deemed avoidable, and 11 were due to avoidable anesthesia complications.[15] Another report from Togo reported a mortality rate of 1:250 and found less than half of the 26 facilities surveyed had pulse oximetry, and none had capnography.[70] In a national report on maternal mortality in South Africa, nearly 2.35% of recorded maternal mortalities were anesthesia related, and the majority (93%) were deemed avoidable. One of the most common causes of anesthesia death in this report was the provision of spinal anesthesia without skills necessary to manage an airway or convert to general anesthesia.[71] Other commonly cited causes of avoidable anesthesia mortality in resource-constrained settings include inadequate staffing, monitoring, and drug overdose. A recent meta-analysis of anesthesia-related maternal mortality in LMICs found the risk of death from anesthesia for women undergoing obstetric procedures to be 1.2 per 1000 (vs. 3.8 per million in the United States), with higher risk reported if general anesthesia was used or if anesthesia was provided by a nonphysician[72]. In this analysis, anesthesia was the cause in 2.8% of maternal deaths in LMICs and 13.8% of all deaths during or after C-section in LMICs. To state this differently, anesthesia-related maternal mortality is 300-fold higher for neuraxial and 900-fold higher for general anesthesia than is reported in the United States.

It is important to note that the relationship between hospital-based perioperative morbidity and mortality and surgical disease morbidity and mortality must be interpreted with caution in settings where patients lack access to hospitals. In other words, in an HIC a patient's chances of dying from a ruptured viscous are roughly the same as the chances of dying from surgery for a ruptured viscous because more than 95% of the population has access to care. However, in an LIC, while the perioperative mortality for a ruptured viscous may be 10%, the majority of patients with this condition never make it to surgery and have mortality rates that are dramatically higher.

Affordability is another significant barrier to accessing surgical and anesthesia services. Each year, approximately 33 million people face catastrophic out-of-pocket expenditure due to payment for surgery and anesthesia (Fig. 2.8) with an additional 48 million people facing catastrophic expenditure related to non medical costs of accessing surgical care (e.g., transportation, lodging, and food).[5,73] Nearly half (3.7 billion) of the world's population is at risk of catastrophic expenditure if they were to have surgical and anesthesia care. The majority of those at risk live in

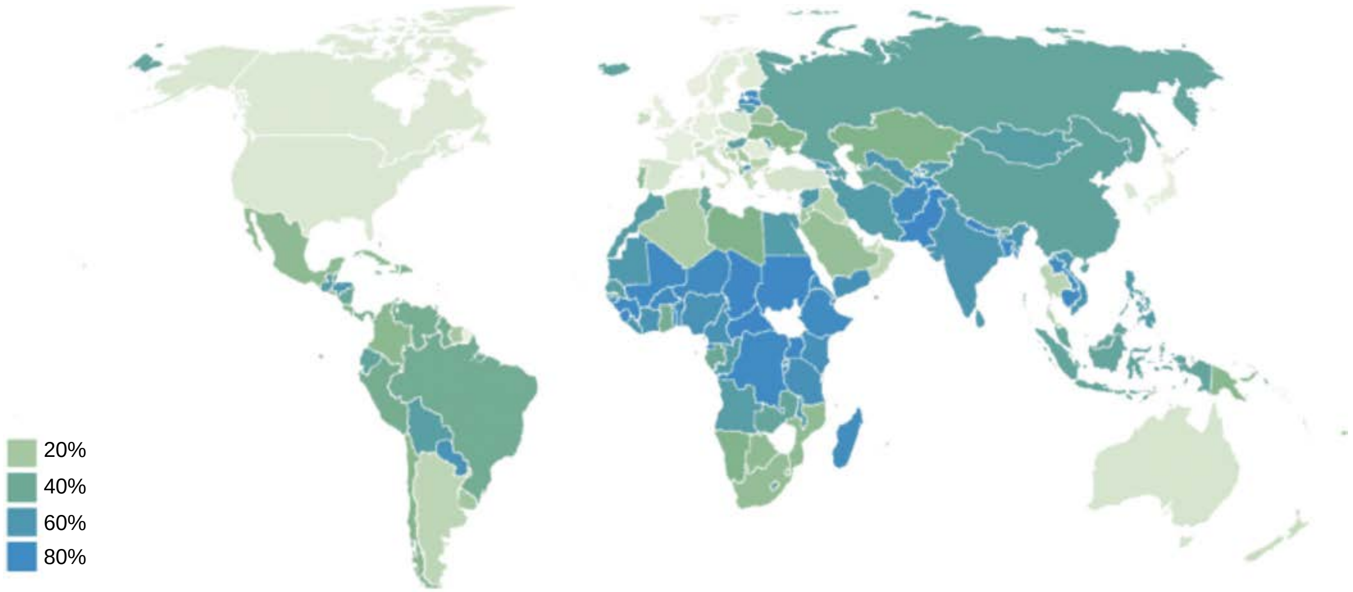

Fig. 2.8 **Risk of catastrophic expenditure for surgical care in 2014 (% of people at risk).** (Data from http://databank.worldbank.org/data/home.aspx. sub-Saharan Africa, and South and Southeast Asia. The issue of affordability applies not only to surgery itself but also to components of perioperative care including analgesia and transfusions.[74] For example, in South America, a monthly prescription of opiate for chronic pain may cost 200% of annual income.[57] In India (where nominal gross national income per capita is $1670), a unit of blood often costs up to $247 despite a legal limit of $25.[75,76] Global health and development leaders including the WHO and World Bank prioritize financial risk protection as a key component of achieving universal health coverage goals for all countries. Despite relatively high out-of-pocket costs at the individual level for some procedures, surgery is a highly cost-effective public health intervention as discussed further in the following sections.

GLOBAL ANESTHESIA, SURGERY, AND PAIN CRISES: ORIGINS AND AREAS FOR INTERVENTION

Workforce shortages, inadequate infrastructure, lack of policy and prioritization, and increasing burden of surgical disease are among many factors contributing to current limitations in access, affordability, and safety of anesthesia and surgical services worldwide.[77] As previously discussed, global industrialization and an "epidemiological transition" in many LMICs have resulted in rising noncommunicable disease and injury burdens with lagging investment to address these issues. While these fundamental imbalances between healthcare needs and healthcare resources underlie much of the current global surgery, anesthesia, and pain crises, several additional factors have also contributed.

Misperceptions and Limited Data

Two common misperceptions about surgery and anesthesia have contributed to the delayed recognition of these fields as global public health priorities: (1) the scope and scale of surgical disease and pain burdens were vastly underestimated; and (2) surgical and anesthesia care were erroneously assumed to be too expensive and technology dependent to be done safely or cost-effectively in resource-constrained environments. In this section we discuss reasons why the surgical disease and pain burdens are historically poorly characterized. Misperceptions about cost-effectiveness and feasibility of safe surgery and anesthesia care also have roots in a historical data void, especially from LMICs.

Several innovative service delivery models in the public and private sectors of LMICs (e.g., Indus hospital, Aravind Eye Hospitals, and Narayana Hrudayalaya Heart Hospital) have demonstrated that it is feasible to provide cost-effective, safe, and affordable surgical and anesthesia care in resource-constrained countries.[78–81]

Recent data have consistently demonstrated that surgical services are among the most cost-effective public health interventions (Fig. 2.9). There are several methods to define cost-effectiveness thresholds, each with pros and cons.[82] One of the most commonly cited methods uses GDP-based thresholds. This approach was suggested by the WHO Commission on Macroeconomics and Health and has been defined by authors from the WHO's Choosing Interventions that are Cost–Effective project (WHO-CHOICE) as, "interventions that avert one DALY for less than average per capita income for a given country or region are considered very cost–effective; interventions that cost less than three times average per capita income per DALY averted are still considered cost–effective; and those that exceed this level are considered not cost–effective."[83]

In 2003 in Bangladesh, one of the earliest cost-effectiveness studies on surgical care reported the cost of emergency obstetric care at less than $11 per DALY averted.[16] This was 3 times more cost-effective than the measles vaccine (in 2003 dollars). The DCP2 and DCP3 demonstrated cost-effectiveness of the first-level surgical hospital, with essential surgical services all being highly cost effective and many

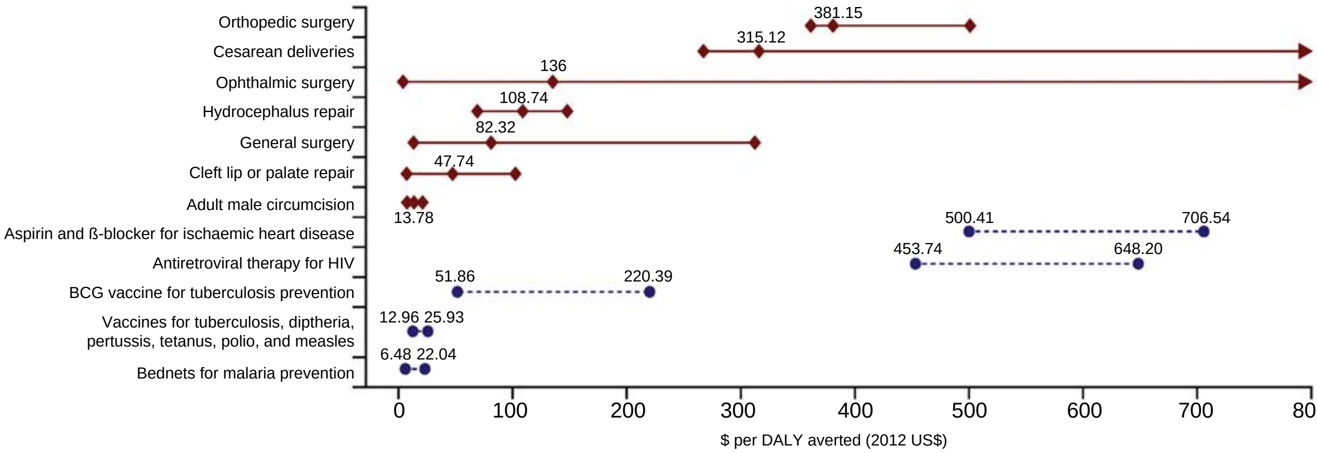

Fig. 2.9 Cost-effectiveness of surgery in low-income and middle-income countries compared with other public health interventions. Data points are medians, error bars show range. (Source: Chao TE, Sharma K, Mandigo M, et al. Cost-effectiveness of surgery and its policy implications for global health: a systematic review and analysis. *Lancet Glob Health*. 2014;2:e334–e345. Copyright © 2015 Elsevier Ltd. Creative Commons Attribution License [CC BY].)

costing $10 to $100 per DALY averted. This is comparable to the cost-effectiveness of other public health interventions such as immunizations ($13-$26 per DALY) or bed nets for malaria prevention ($6-$22 per DALY), and much more cost-effective than other high-priority public health interventions such as HIV treatment ($500 per DALY).[84] A recent analysis of the cost-effectiveness of a pediatric operating room in Uganda found a cost of $6.39 per DALY averted and $397.95 per life saved, with a net economic benefit of over US$5 million per year (cost of $41,000 per year).[85]

In a 2012 forum hosted by the Copenhagen Consensus, five leading health economists, including four Nobel laureates, were asked how best to spend US$75 billion over 4 years to “advance global welfare,” especially in LMICs. The leading priority identified by the group was the expansion of surgical care capacity (US$3 billion per year).[86]

In the past 5 years the global surgery and anesthesia communities have expanded the volume of data that dispel prior misconceptions and support prioritization of surgical and anesthesia care in the global health agenda. During this timeframe, there has also been an explosion of articles that expand available data on a wide range of global anesthesia and surgical topics. The majority of these articles have been published in the surgical journals though recently anesthesia publications have begun to actively support global anesthesia research. The global anesthesia community must increase research productivity in global health and also invest in advocacy, policy, and implementation sciences in order to ensure impact.

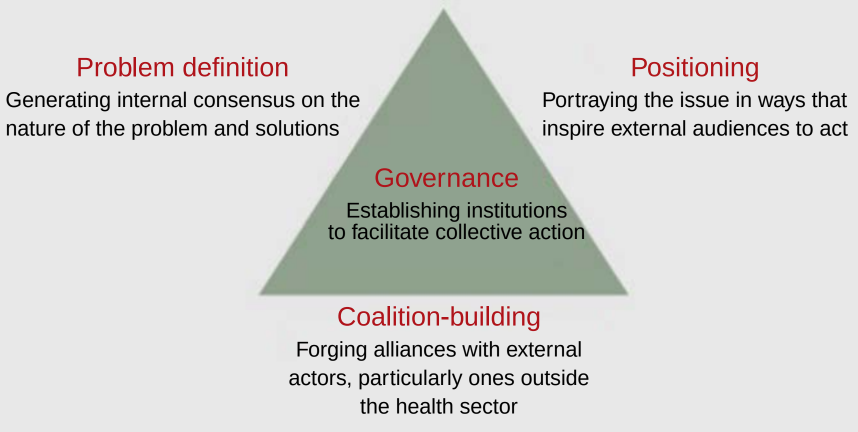
Advocacy and Policy

There are many reasons why surgery, anesthesia, and pain have historically not been prioritized by national health systems, donors, or the broader global health community. Although surgical disease accounts for 30% of global disease burden, less than 1% of development assistance for health supports delivery of anesthesia and surgical care.[87] Imbalance between resource allocation and disease burden is found in many health conditions, though the degree of this disparity for surgical disease and pain is particularly striking.

As discussed previously, lack of disease burden data and misperceptions about safety and cost-effectiveness have significantly hindered advocacy efforts for global anesthesia and surgery. In a qualitative analysis of factors that have hindered political prioritization for global surgery, several additional factors were identified including: fragmentation of the global surgery community, lack of leadership and consensus, and inadequate political strategy (e.g., not capitalizing on opportunities such as the MDGs).[88] In another analysis to determine why certain disease-specific global health networks are relatively more or less effective than others, four common challenges were highlighted, each with relevance to global anesthesia and surgery: (1) defining the problem and how it should be addressed; (2) positioning the issue in a way to inspire action by external audiences; (3) building coalitions that include stakeholders outside the healthcare sector (coalitions are too often dominated by HIC providers); and (4) creating governance institutions that facilitate collective action (Fig. 2.10).[89] Another study that examined factors influencing prioritization of surgery in national health systems concluded that sustained advocacy, effective framing of problems and solutions, robust country-level data, and support from regional and international partners were critical for success but often lacking.[90]

Advocacy efforts for surgery, anesthesia, and pain face a few additional and relatively unique challenges. Unlike infectious diseases such as HIV or Ebola, surgical disease and pain are not pandemic and do not incite similar action by the HIC donor community. Furthermore, most surgical conditions and pain are difficult to advertise and are not disease specific. While select pediatric conditions (e.g., cleft lips) are easily marketable, other conditions like trauma, hernias, and cesarean section are more difficult to compassionately portray in media in attempts to improve public awareness.

The WHA resolution 68.15 emphasized advocacy and resource development in five key focus areas for global surgery (workforce, essential medicines, information management,



Problem definition
Generating internal consensus on the nature of the problem and solutions
Positioning
Portraying the issue in ways that inspire external audiences to act
Governance
Establishing institutions to facilitate collective action
Coalition-building
Forging alliances with external actors, particularly ones outside the health sector

Fig. 2.10 Four challenges that global health networks face. (From Shiffman J. Four challenges that global health networks face. *Int J Health Policy Manag.* 2017;6[4]:183–189. service delivery, and advocacy). The LCOGS provided clear framing of problems (see Box 2.2), outlined priorities for country-level data collection, and helped to provide frameworks for national surgical, obstetric, and anesthesia plans (NSOAPs) in LMICs. As more NSOAPs are produced, they have the potential to serve as key rallying points for national advocacy efforts.

Anesthesia, surgery, and pain need global champions. Only recently has advocacy by leading global organization (e.g., the World Bank, WHO) and select local governments in LMICs focused attention on anesthesia and surgery in the global context. This is in part due to advocacy efforts by several relatively recent initiatives (e.g., LCOGS, The Global Alliance for Surgical, Obstetric, Trauma, and Anaesthesia Care [G4 Alliance], WFSA, GICS, and several more). These multidisciplinary efforts must be expanded and sustained in order to reach the critical mass needed to overcome prior misperceptions and affect change. It is essential that advocacy efforts for surgery, anesthesia, and pain be consistent with the key messages of LCOGS, the Global Health 2035 Report, WHA resolution 68.15, and the SDGs, and emphasize that anesthesia, surgery, and analgesia are indispensable components of "universal health coverage." No longer can surgery be seen as a vertical (i.e., disease-specific) program.

One key objective for advocacy efforts will be to identify new streams of funding from global donors, national budgets, private sectors, and innovative models. Similar to the large-scale funding initiatives to combat HIV/AIDS and other infectious diseases (e.g., the U.S. President's Emergency Plan for AIDS relief, Gavi Vaccine Alliance, The Global Fund), surgery and pain require comparable attention and support. In addition to domestic and international financing mechanisms to support health system scale-up, public-private partnerships and innovative patient-level financial risk protection strategies must be integral components to advocacy efforts.[5]

As leaders in safety, pain, perioperative care, and more, the global anesthesia community must actively engage in policy, research, and innovative global initiatives to expand access to quality care. Academic institutions from all countries can play a significant role in supporting a coordinated research agenda, creating a global voice for advocacy, sharing information, and harmonizing educational standards and opportunities. Anesthesia must follow the lead of other medical disciplines to not only cultivate but also support faculty and trainees with interests in global public health careers. Such advocacy will likely require coordination and partnership with multiple disciplines, including nonphysician provider cadres who perform a significant proportion of anesthesia services, especially in LICs.[91]

Workforce Shortages and Strategies for Expansion

The critical shortage of trained anesthesia providers in resource-constrained settings is one of the most significant barriers to expanding access to safe surgical, anesthesia, and pain services for billions of people worldwide. Although shortages of many key members of the surgical workforce exist (including surgeons, obstetricians, pathologists, radiologists, laboratory technicians, nurses, biomedical engineers, and more), anesthesia provider shortages in LMICs are particularly striking and relatively neglected. Countries like the Central African Republic have no physician anesthesiologists and only 24 nonphysician anesthesia providers (NPAPs) for a population of nearly 5 million. Ethiopia, with a population of over 100 million people, has only 35 physician specialist anesthesiologists. A survey of emergency obstetric care capacity at facilities in Uganda found that lack of staff had the greatest correlation with observed mortality rates.[92] In a survey of 64 public and private hospitals in Uganda, 84% did not have a physician specialist anesthesiologist, and 8% had no trained anesthesia providers at all.[93] In another survey of anesthesia providers from five main referral hospitals in East Africa (Uganda, Kenya, Tanzania, Rwanda, and Burundi), only 7% reported adequate anesthesia staffing.[94] In settings where providers exist but in small numbers, the workforce shortage is compounded by heavy administrative burdens and non-clinical duties.

While the anesthesia workforce shortage is most severe in LICs and particularly pronounced in sub-Saharan Africa, regional workforce shortages also exist in HICs and can significantly limit access to care for rural populations.[95,96] In one survey of rural hospitals in the United States, 36% reported delay or cancellation of surgery due to a lack of anesthesia providers.[97] Data from HICs demonstrate differences in trauma

mortality are significantly worse starting at five miles from a trauma center in a major urban city.[98] One can only imagine outcome differences in settings where there may be no surgical or anesthesia provider for tens or even hundreds of miles.

The optimal number of specialist surgical, anesthetic, and obstetric workforce (SAO) providers needed to give access to safe surgery is unknown and likely to vary significantly based on local resources and needs. The SAO density correlates with life-expectancy and in one study, as SAO providers increased from 0 to 20 per 100,000 population, maternal mortality decreased by 13.1% for each 10 unit increase in provider density (Fig. 2.11). These benefits were also observed with workforce expansion beyond 20, though with less magnitude beyond 30 and 40 providers per 100,000 (Fig. 2.12).[99] Based on these findings, the LCOGS recommended prioritizing expansion of the SAO workforce to 20 per 100,000 population by 2030, with anesthesia-specific targets of 5 to 10 anesthesia providers per 100,000.[100]

The density of SAO providers has been estimated at 0.7 per 100,000 population for LICs as compared with 56.9 per 100,000 population for HICs.[101] Worldwide, 77 countries report an anesthesia provider density less than 5 per 100,000, with a 90-fold difference between the average physician workforce density in HICs as compared to LICs. The anesthesia workforce crisis is most severe in sub-Saharan Africa, where most countries have approximately 1.0 physician anesthesiologist per 100,000 population as compared to approximately 19 in Europe or 21 per 100,000 in the United States (Fig. 2.13).[100] Twenty-six countries in sub-Saharan Africa reported less than 0.5 physician anesthesia providers (PAPs) per 100,000. In many LICs, NPAPs provide the majority of anesthesia care. When NPAPs are included in calculations of total anesthesia provider density, 16 countries in sub-Saharan Africa still report less than 1 anesthesia provider per 100,000, and worldwide 70 countries still report less than 5 anesthesia providers per 100,000 population. Estimates from the WHO Global Surgical Workforce database demonstrate that 12% of the SAO workforce provides care for approximately a third of the world's population.[101] Worldwide, LICs and LMICs have 48% of the world's population but only 20% of the SAO workforce.

Multiple factors have contributed to the ongoing surgical and anesthesia workforce crises in LMICs, including limited training infrastructure, relatively low professional status, lack of career advancement (especially for NPAPs), perceived limited job opportunities relative to other professions (e.g., infectious disease in LMICs), cost of training, inefficient hiring mechanisms, provider burnout, as well as internal (e.g., private practice in urban settings) and external brain drain (e.g., leaving the country).[102,103] Lack of consensus on anesthesia practice models and polarized views on who should provide anesthesia care (i.e., physician versus nonphysician, supervised versus independent) are additional factors limiting a clear path for rapidly scaling the global anesthesia workforce (Table 2.3).[91] Task-sharing is a prominent and controversial component of many surgical workforce expansion efforts.

Each of the aforementioned challenges must be addressed as part of any national or international effort to expand the anesthesia workforce. The long-term goal of building robust training infrastructures in low-resource settings requires locally led plans for national advocacy, implementation, and evaluation. Such efforts can benefit from international investment and collaboration.[104-108]

Significant heterogeneity in anesthesia care models exists worldwide. Although the varied anesthesia practice and training models have evolved to address different local needs and challenges, excess heterogeneity and lack of consensus on anesthesia workforce strategy may provide an additional challenge to global workforce expansion. For example, within sub-Saharan Africa, formal nonphysician training programs range from 3 to 72 months in duration with widely different entry requirements, no standardized curricula or assessment tools, and different scopes of practice. For countries seeking

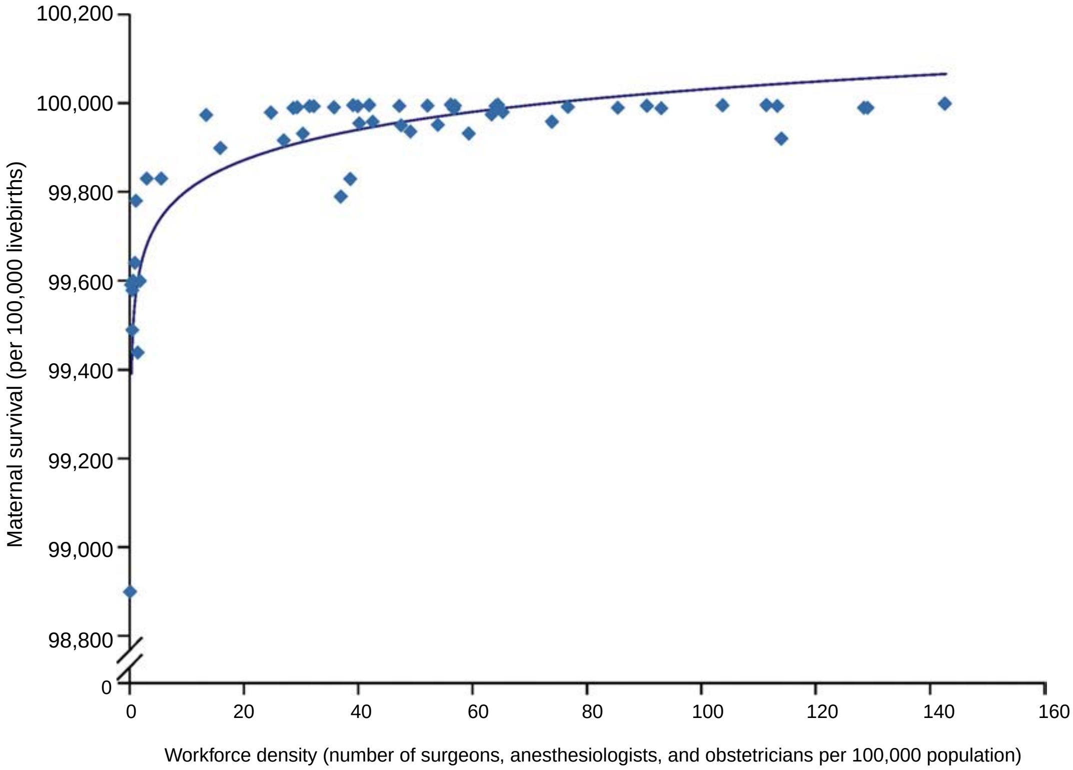

Fig. 2.12 Specialist surgical workforce density and maternal survival. A surgical workforce density of less than 20 per 100,000 specialist surgeons, anesthesiologists, and obstetricians correlates with lower rates of maternal survival. Maternal survival per 100,000 livebirths = 98,292 × ln (workforce density) + 99,579. (From Meara JG, Leather AJ, Hagander L, et al. to increase anesthesia provider numbers, no clear roadmap exists. In most of these countries, task-sharing with NPAPs will likely play a key role in workforce expansion efforts. Collaborative efforts involving stakeholders from different countries and different anesthesia provider cadres can support anesthesia workforce expansion efforts by offering frameworks for anesthesia training, competency assessments, and potential practice models that are feasible with local resources and that meet local needs. Initiatives that ensure quality (e.g., education programs, credentialing bodies, and licensing exams) are as important as those that focus on increasing absolute numbers. The global anesthesia community can play a significant role via advocacy, research, education, and partnership to address many of the challenges that have created the current global anesthesia workforce crisis.

Infrastructure Challenges

The provision of surgical and anesthesia care requires infrastructure that is often lacking in many LMICs. As discussed elsewhere in this chapter, such infrastructure does not necessarily need to be high-cost or based on advanced technologies to provide safe care. In addition to the provider shortages already discussed, additional infrastructure challenges that frequently limit surgical and anesthesia service delivery include: underdeveloped patient referral and prehospital systems, medication and equipment shortages, and inadequate supply chains and facility resources.

In maternal health, and more recently for surgery and anesthesia, a "three delays framework" has been used to describe factors delaying timely access to safe healthcare services.[5] The "first delay" in this model (delay in seeking care) may occur due to financial, cultural, education, or other patient factors. Anecdotally, fear of bad surgical outcomes (whether true or not) and more specifically a fear of anesthesia may also contribute to the "first delay." The second and third delays are more directly linked to infrastructure limitations. The "second delay" (delay in reaching care) occurs when health facilities cannot be reached in a timely manner and may be due to geographic distance or challenges with transportation (e.g., bad road conditions, no access to a car, no money for public transport). Although efforts to improve healthcare infrastructure often focus on facility-based interventions, emphasis on infrastructure that minimizes this "second delay" is underappreciated despite evidence of cost-effectiveness.[109] For example, the lack of prehospital care systems in many LMICs is a significant source of avoidable morbidity and mortality. The DCP3 estimates that 4.7 million deaths in LMICs each year are due to surgical conditions that are potentially addressable through prehospital and emergency care systems. In Uganda, less than 25% of the population lives within 2 hours of a surgical facility, and worldwide approximately 2 billion people lack access due to this second delay.

When discussing infrastructure limitations, most people think of the "third delay" (delay in receiving care), which occurs when patients reach a facility but may not receive adequate care because of limitations in facility resources. Data from 800 first-level health facilities in LICs demonstrate that relatively few first-level hospitals could provide C-sections (64%), laparotomies (58%), or open fracture repairs (40%), and most did not have reliable electricity (31%), running water (22%), oxygen (24%), or Internet access. Without reliable utilities, standard equipment like monitors, ventilators, anesthesia machines, and autoclaves are often not functional, assuming they are even present at all. In recent years, the number of surgical and anesthesia capacity assessment tools increased significantly, although most tools have focused on surgical care with limited ability to assess anesthesia or analgesia capacity.[110–117]

The WHO Surgical Safety Checklist includes requirements for pulse oximetry, anesthesia machine check, and confirmation of instrument sterility, yet these may not currently be feasible in many LMIC health facilities. As the consensus on what constitutes "essential" or "standard" anesthesia and surgical safety equipment is evolving, it is universally agreed that far too many health facilities face routine shortages of even the most basic anesthesia equipment.

Inadequate access to indicator strips, maintenance support, power, and distilled water result in low compliance with the 2016 WHO/Pan American Health Organization (PAHO) standards for cleaning, disinfection, and sterilization in most LMICs.[118,119] In a survey of 28 district hospitals in Zambia, 35% did not have a laryngoscope.[120] A study from Nigeria found that most facilities could not provide general anesthesia (53%); another survey in the Democratic Republic of Congo demonstrated 40% of hospitals lack suction, and in Guatemala only 17% of facilities surveyed had capnography.[121,122] In Uganda, a 2014 survey of health facilities that offer emergency services and surgical care revealed only 22% had pediatric airway equipment, 41% adult airway equipment, and 28% a pulse oximeter.[123] In one survey about obstetric operating room capacity in the five main referral hospitals in East Africa (Uganda, Kenya, Tanzania, Rwanda, and Burundi), only 4% of the providers surveyed reported the presence of electrocardiograph (ECG), pulse oximetry, continuous blood pressure monitoring, capnography, thermometer, stethoscope, difficult airway cart, suction machine, recovery room, and intensive care unit (ICU) facilities.[94] Access to reliable oxygen is a common problem in resource-constrained health systems. In such settings, oxygen is rarely available through central pressurized gas lines and more often provided via tanks or oxygen concentrators, the latter of which has been shown to offer long-term cost savings and increased reliability.[124] (Further discussion of oxygen supply challenges in resource-limited settings is provided in the section, Essentials for Practice in Resource-Constrained Settings of this chapter)

Equipment donations are common in LMICs, however, they often have limited long-term impact and multiple unintended consequences. Donations are frequently made with limited understanding of local needs, lack of communication between donor and recipient, and absence of ongoing technical support or access to consumables. Well-intentioned donors are often unaware of WHO Guidelines for Medical Device Donation, or of the fact that purchase costs account for only 20% of total lifetime costs for a piece of equipment.[125] As a result, up to 30% of donated equipment may only transiently or never become operational, and commonly accumulates in equipment graveyards because of a sense of obligation by recipients to not throw anything away. For example, donations of modern anesthesia machines from HICs is commonly encountered in many LMICs. Without reliable power, pressurized gas supplies, biomedical support, or access to disposables (e.g., carbon

BOX 2.3 World Health Organization Essential Medicines List—Anesthesia Medications

General Anesthetics and Oxygen

- Halothane, isoflurane, nitrous oxide
- Oxygen
- Ketamine
- Propofol (or thiopental)
- Bupivacaine
- Lidocaine

Muscle Relaxants

- Atracurium
- Neostigmine
- Suxamethonium
- Vecuronium
- Pyridostigmine*

Preoperative Medication and Sedation for Short-Term Procedures

- Atropine
- Midazolam
- Morphine

Medicines for Pain and Palliative Care

- Acetylsalicylic acid
- Ibuprofen
- Paracetamol
- Codeine
- Fentanyl transdermal (for cancer pain)
- Morphine
- Methadone
- Dexamethasone
- Amitriptyline
- Diazepam
- Haloperidol
- Ondansetron

Additional Medications†

- Epinephrine
- Hydrocortisone
- Naloxone
- Lorazepam
- Enoxaparin
- Heparin
- Tranexamic acid
- Digoxin
- Verapamil
- Amiodarone*
- Hydralazine
- Lasix
- Sodium nitroprusside*
- Dopamine*
- Mannitol
- Insulin
- Glucose
- Ergometrine
- Misoprostol
- Oxytocin
- Misoprostol*

Notable deletions

- Ether (2005)
- Ephedrine (1995)*
- Magnesium sulfate (1988)
- Pethidine (2003)

*Ephedrine is listed in the complementary list of medications in the 2017 20th Edition EML. The complementary list presents essential medicines for priority diseases, for which specialized diagnostic or monitoring facilities, and/or specialist medical care, and/or specialist training are needed.

†Blood products, antiseptics, and antibiotics are included in the EML and not listed here.

Data from http://www.who.int/selection_medicines/committees/DELETIONS.pdf?ua=1.https://www.who.int/medicines/publications/essentialmedicines/20th_EML2017.pdf?ua=1/.

dioxide absorbent, humidity filters, circuit tubing), it is sometimes hard to argue in favor of these machines.

Reliable access to medications and blood are two additional common infrastructure challenges limiting access to safe surgery and anesthesia services worldwide. The WHO Essential Medicines List includes medications to safely perform general anesthesia, monitored anesthesia care (MAC), neuraxial, regional, local anesthesia, as well as acute and chronic pain management (Box 2.3).[126] Despite the existence of the list for more than 40 years, critical shortages of many medications persist. A WHO survey of all health facilities in Uganda examined availability of twelve anesthetic drugs (atracurium, bupivacaine, halothane, isoflurane, desflurane, sevoflurane, ketamine, lidocaine 2%, lidocaine 5% heavy spinal injection, midazolam, nitrous oxide, and suxamethonium) and found that only 2% of the surgical health facilities had all of these medications and only 19% had half.[123] The same WHO survey in the Democratic Republic of Congo found that only 33% of hospitals had bupivacaine, 21% thiopental, and 16% halothane. Factors specifically affecting access to analgesics are discussed further in the next section, though supply chain, cold storage, and cost are common challenges that limit availability for many drugs. Drug quality is also a factor in some LMICs where variable manufacturing quality and fraud (i.e., counterfeiting) are commonly encountered.[127] It is estimated that 1 in 10 medical products (e.g., medications) found in LMICs are substandard or falsified and result in hundreds of thousands of deaths each year.[128,129]

The WHO Essential Medicines List also includes blood products. Despite more than four decades of global advocacy (1975 WHA28.72) for universal access to safe blood, limited transfusion capacity significantly impacts the ability to provide safe surgery and anesthesia care, especially for rural and LMIC populations. Most rural surgical facilities are unable to provide consistent access to safe blood. Patients lack timely access to safe blood as a result of several common challenges including inadequate blood supply, distribution networks, rural blood banking capacity, safety protocols, workforce (e.g., pathologists, laboratory technicians), testing supplies, and policy implementation, as well as high costs of blood and high prevalence of infectious diseases.[75,130,131] The whole blood donation rate is used as an indicator of blood availability. The LCOGS recommends a minimum of 15 blood donations per 1000 people per year, yet this rate is 4.6 per 1000 people per year in LICs (compared with 32.1 per 1000 people per year in HICs).[5,132] Most LMICs cannot maintain adequate supply from voluntary non-remunerated donors (VNRDs) alone (as advocated by WHO), and the use of paid donors or family donors poses numerous logistic and safety concerns.[75] According to WHO data, 71 countries collect the majority of their blood supply from family or paid donors, 50% lack capacity to separate blood components, and 23.5% of countries have less than 100% screening for at least one of these transfusion-transmissible infections: HIV, hepatitis B, hepatitis C , or syphilis.[132] For many LMICs, investment in transfusion infrastructure, expansion of transfusion research, and advocacy (including rethinking of well-intentioned but context-limited policies such as VNRD-only mandates, requirements for onsite pathologists, and mandatory replacement units) are critical areas for engagement by anesthesia providers in the greater global health community.[75,133]

There is an evolving consensus on global standards for anesthesia equipment, medications, and other infrastructure.[3,117] As a result, most assessments of facility or national capacity capture different data that may over- or underestimate current infrastructure limitations. For example, lack of access to rocuronium, sevoflurane, or propofol does not necessarily indicate inability to safely perform anesthesia if suxamethonium, halothane, isoflurane, or thiopental are available. Currently efforts are underway by the WFSA, GICS, and other organizations to develop anesthesia-specific research tools to assist LMICs in monitoring and evaluation of anesthesia capacity.[116,117] The global anesthesia and surgical communities are likely to benefit from continued collaboration and harmonization of efforts that assess global anesthesia infrastructure.

Inequities in Analgesia

Five billion people worldwide have little or no access to analgesia. As with the surgical disease crisis, inequities in analgesia access are in part a result of the limited availability of data that quantify the problem. Unlike most traditional global health metrics that focus on extending healthy life and productivity, alleviating pain may not always target these same goals (e.g., acute surgical pain relief and palliative care), thus adding to the complexity of quantifying pain burden. Massive inequities in access to analgesia are also attributed to several additional factors including advocacy challenges (pain is not disease specific or easy to associate with a "face"), limited training opportunities for healthcare professions, fear of addiction and diversion, financing, supply chain limitations, cultural attitudes, and regulatory and legal barriers (Box 2.4).[52,53] In the ensuing discussion, we consider some of these barriers and potential areas for intervention by the global anesthesia community.

Limited financial resources and infrastructure hinder the ability of healthcare systems to deliver analgesia (i.e., effective supply chains) and limit the ability of patients to afford such care. Countries with a lower GDP or human development index have less access and use of opiates.[53] Opiate prices in LMICs are often significantly higher relative to GDP. In the recent past in Argentina and Mexico, the monthly cost of an opioid prescription for oncologic pain was reported to be more than 200% the average monthly income.[74,134] In Rwanda, the reported price of injectable morphine is 6 times the lowest cost reported in the International Drug Price Indicator Guide.[30,135] Drivers of these inflated prices include import costs, taxes, licensing fees, storage and sales restrictions, and limited public finance programs. International regulations and misconceptions about pain treatment and addiction form the basis for many of these interventions.

BOX 2.4 Factors Affecting Access to and Availability of Analgesia

Knowledge and Attitudes

- Providers—limited training
- Patients—limited health literacy
- Opiophobia—fear of addiction, diversion, or side effects
- Cultural attitudes and beliefs about pain
- Limited data to estimate pain burden or accurate national analgesia needs
- Challenging advocacy (pain is not disease specific or easy to associate with a "face")

Regulations and Policy

- Prohibitionist bias
- Implementation requires significant resources
- Onerous regulations (e.g., limits on who can prescribe, duration, dose and indication)
- Complex regulations create fear of prosecution among providers
- Limited global advocacy efforts to expand analgesia access

Economics and Financing

- Poverty
- Relatively high analgesic costs in LMICs
- Costs of implementing/enforcing international regulations
- Few mechanisms for financial protection from analgesic costs (e.g., subsidies or UHC)

Health Systems

- Supply chains (timely import, procurement, storage, and distribution)
- Limited analgesic options
- Few providers trained/skilled to provide adequate analgesia
- Inadequate number/distribution of facilities providing analgesia care
- Limited national government capacity

LMIC, Low- and middle-income countries; *UHC*, universal health coverage.

Modified from: Berterame S, Erthal J, Thomas J, et al. Use of and barriers to access to opioid analgesics: a worldwide, regional, and national study. *Lancet.* 2016;387(10028):1644–1656.

INCB 2017 report https://www.incb.org/documents/Publications/AnnualReports/AR2017/Annual_Report/E_2017_AR_ebook.pdf.

Misinformation about analgesia has biased knowledge and attitudes among providers, patients, and policymakers, and has resulted in significant undertreatment of pain. Several studies have demonstrated that the risk of addiction associated with appropriate analgesic administration is significantly exaggerated and especially low for acute, oncologic, or end-of-life pain.[136] Nonetheless, widespread and excessive fears over diversion and addiction have resulted in unnecessarily onerous regulatory barriers that often confuse tolerance and dependence, users and addicts, and disproportionately affect poor and marginalized populations.[137] In China, for example, a domestic ketamine abuse problem has led to repeat lobbying of the International Narcotics Control Board (INCB) by the Chinese government to reschedule ketamine as a schedule I drug for all countries. Such regulation would effectively remove the nearly ubiquitous access to ketamine in LMICs, and further exacerbate the ongoing global pain crisis.[138] Ketamine is inexpensive, accessible, and safe, and as a result has become a critical resource for the provision of safe and accessible anesthesia and analgesia services worldwide. Fortunately, attempts to restrict ketamine have been promptly recognized as heartless and a violation of international regulatory policies.

Tramadol is another analgesic with frequently misunderstood pharmacology that is commonly found in LMICs. Tramadol is not controlled by international regulations, which has led to its widespread availability for analgesia but also to its abuse.[139] Abuse is widely reported in many HICs (e.g., Canada) and LMICs (e.g., many countries in Africa and the Middle East) and is so severe that in countries like Cameroon, it can literally be found in the groundwater as a result of human excretion.[140] Tramadol is not considered an adequate substitute for opiates and is not included in the WHO Essential Medicines List.

Contemporary legal and regulatory/policy frameworks have significantly exacerbated disparities in access to analgesia care. In the wake of several key events in the 1800s that fueled skyrocketing opioid abuse, including the Opium Wars and invention of the hypodermic syringe, the beginning of the 20th century produced several of the first national and international efforts to restrict and regulate narcotics. This included the first international conference on narcotics in 1909 (International Opium Convention in Shanghai) and the first multilateral drug treaty in 1912 (The Hague Opium Convention). One of the most notable regulations of the 20th century is the 1961 UN Single Convention on Narcotic Drugs. The opening sentence of the "Single Convention" recognizes, "…that the medical use of narcotic drugs continues to be indispensable for the relief of pain and suffering and that adequate provision must be made to ensure the availability of narcotic drugs for such purposes…" The Single Convention set out to control the use and trade of plant-based drugs (opium, cannabis, and cocaine) while also assuring availability for medical purposes.[141] This regulation mandated government participation (reporting national estimates of narcotic needs, meticulous record keeping), regulated drug cultivation, restricted trade to authorized international parties, and created the INCB. The INCB was tasked with monitoring UN drug convention implementation and required each country to designate an enforcement office (e.g., the Drug Enforcement Administration [DEA] in the United States). While most countries adopted this onerous regulation, most poor countries did not have the extensive resources needed to enact all of these changes. The Single Convention's "global estimates" system has been particularly difficult for many countries to implement. This system requires all countries to provide an estimate of opiate need (for medical purposes) in order to inform global production goals and limit excess opiate supplies that are at risk for illicit use. Accurate estimates require significant resources, and for many LMICs, inability to provide accurate estimates translates directly to inadequate supply. For example, 2017 opiate estimates for Chad (population 14.5 million) predicted 341 g fentanyl, 249 g morphine, and 105 g codeine. When compared to estimates from Canada (population 36.3 million: 150,000 g fentanyl, 4,750,000 g morphine, 40,020,000 g codeine, and 70 other controlled substances) the disparity and gross underestimation is apparent.[142] By approving such gross underestimates, the INCB effectively is legally prohibiting patients from having access to opiates. In times of humanitarian crisis, the Single Convention impedes the ability to emergently augment local analgesia capacity as became evident in the wake of the 2010 Haiti earthquake.[143]

Global regulations to curb illicit use have dominated efforts to ensure access to analgesics for medical purposes (or to ensure access to substance abuse treatment). In 1985, the Parliament of India passed the Narcotic Drugs and Psychotropic Substances Act to enforce international drug policy (e.g., the Single Convention). The Act's onerous regulations and extreme penalties (including the death penalty for certain drug-related crimes) resulted in more than a 90% decrease in the medicinal use of morphine.[144,145] This imbalance, referred to by some as "collateral damage from the war on drugs," disproportionately affects LMICs and continues to cripple access to analgesics for the majority of the world's population.[143] Such bias has also impaired scaleup of addiction treatment initiatives. For example, addiction treatment (methadone and buprenorphine) was not added to the WHO Essential Medicines List until 2006, approximately 100 years after the passage of the earliest narcotic regulations and 40 years after the list's creation.

The prohibitory biases of prior international drug policy has resulted in numerous national regulatory barriers that include limitations on who can prescribe, dispense, or administer opiates, as well as limitations on indications (e.g., postoperative but not cancer pain), dosages, or duration of therapy.[137] For example, in Armenia only oncologists with the approval of multiple providers can prescribe outpatient opiates, whereas in the Ukraine, healthcare providers must travel to the patients' homes to administer outpatient opiates. In Jordan, the maximum duration of an opiate prescription for oncologic pain is 10 days, and only three days for all other conditions.[146] These myriad regulations create an additional barrier by inducing fear of prosecution for noncompliance among health professionals, thereby reducing provider willingness to prescribe. Lack of adequate training opportunities for healthcare providers, especially in LMICs, coupled with the rare use of analgesics in clinical practice, create a cycle whereby fewer and fewer providers feel comfortable prescribing opiates.

Several amendments to the Single Convention have been enacted including the 1971 Convention of Psychotropic Substances, the 1988 UN Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances, the inclusion of morphine in the first WHO Essential Medicines List in 1977, and introduction of the WHO Pain Ladder in 1986. Despite these efforts most of the world's population remains without reliable access to analgesia. Nearly 60 years after the Single Convention, the number of drug abusers in many countries is near all-time highs while 150 countries still lack reliable access to analgesia. Even the UN's SDGs, which aim to set development priorities for the world, reflect the prohibitory bias of prior international policies. SDG 3.5 calls for improved prevention and treatment for substance abuse, including narcotics, but fails to mention pain or palliative care anywhere else in the SDGs.[29]

Advocacy and education efforts by the global stakeholders, including the anesthesia community, as well as rethinking of international analgesic policy (including the Single Convention) are essential for progress in addressing the global pain crisis.[125,147] Education for healthcare providers, policymakers, and the public can play a significant role in expanding access to analgesia. Such efforts should focus on pharmacologic treatment strategies, but should also emphasize better understanding and management of causes and contributors to pain, including social and economic determinants. Efforts by numerous Ministry of Health agencies have had small successes. In Vietnam and India, grassroots- and civil-society-led

policy initiatives to allay opiophobia and reduce institutional licensing regulations have significantly increased access to analgesia without an increased diversion.[148–151] In Uganda, advocacy efforts by the nongovernmental organization Hospice Africa Uganda helped convince the Uganda Ministry of Health in 1993 to import morphine powder and to provide domestically made morphine liquid free to all cancer or HIV/AIDS patients. In 2004, the Uganda Ministry of Health legalized opioid prescribing by nurses and clinical officers with palliative care training, which significantly expanded access to analgesia especially in rural communities. The import and domestic packaging of oral morphine for palliative care has translated into greater access to oral morphine for the anesthesia and surgical communities. A similar model is currently being adopted in Rwanda, Nigeria, Kenya, Swaziland, and Malawi.[152]

Section 2: Evolution of Anesthesia Care Models and Challenges Around the World

In the mid-19th century the use of inhaled anesthetics (e.g., most notably ether) began in HICs and spread relatively quickly even to many relatively less resourced countries as a consequence of colonial systems. Today, more than 170 years later, ether is still used in some LICs (Fig. 2.14). The practice of anesthesia has changed significantly, though these changes—including large improvements in patient safety—disproportionately occurred in HICs. The practice of anesthesia varies widely between, and even within, countries. Of the numerous challenges and factors that have shaped this heterogeneity, many are shared by multiple countries regardless of income level. These include common challenges such as inadequate workforce (number, composition, or distribution); high cost of care; limited access for rural and poor populations; and lack of standards for practice and training.

This section explores anesthesiology in six geographic regions of the world, providing examples from countries of diverse economic, political, and population backgrounds. Regional variation in anesthesia care models including key milestones in the development of these systems as well as current challenges they face for providing access to safe, affordable anesthesia care are highlighted. This section is not intended to be comprehensive but to provide examples that are representative of the diversity in anesthesiology despite shared common objectives and many similar challenges.

AFRICA

Africa is the second largest continent, with 1.2 billion people, and the youngest population of all the continents (median age ~19 years vs. 38 years in the United States). Africa is also the poorest continent. Recent estimates by the World Bank demonstrate that 11% of the world's population lives on less than US$1.90 per day, and most of the world's extreme poor (over 400 million people) live in Africa (Fig. 2.15).[153]

Economically, Africa is growing fast with an annual change in GDP for most countries of approximately 3% to 6% (Uganda—an LIC 6.3%, South Africa—an upper middle-income country 1.2%).[154] Total health expenditure (THE) has grown more rapidly than GDP with average increases in THE/GDP from 4.8% in 1995 to 5.9% in 2014 for the continent. Out-of-pocket payments as a proportion of THE have also been decreasing (South Africa decreased from around 17% in 1995 to approximately 5% in 2014, and in Uganda from around 45% to around 40%).[155]

African countries have widely disparate health systems. According to a recently published study on outcomes after surgery in Africa, countries participating in the study reported poor outcomes relative to higher-income regions (despite healthier patients) and attributed worse outcomes to limited resources and lack of access to surgical care.[65] The public healthcare sectors of Uganda and South Africa are, in many ways, representative of the current state of anesthesia and surgical care in Africa.

Uganda (Mary T. Nabukenya and Sarah Hodges)

Uganda (population ~40 million) is one the youngest and most rapidly growing nations in the world (fertility rate

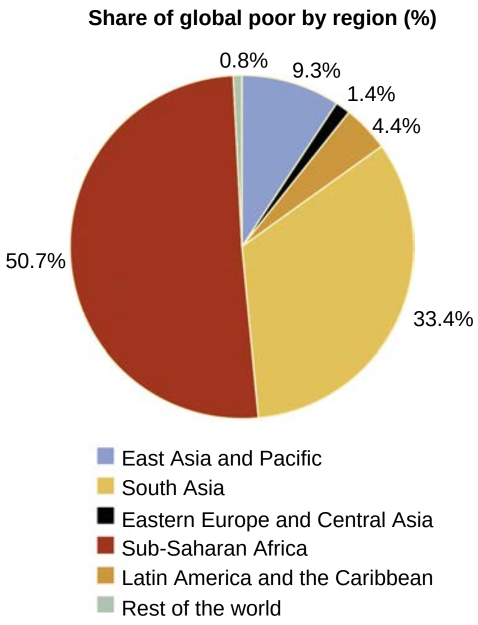

Fig. 2.15 Where are the global poor living? The global poor, by region, 2013. (Source: Most recent estimates, based on 2013 data using PovcalNet [online analysis tool], World Bank, Washington, DC, http://iresearch.worldbank.org/PovcalNet/. [Figure originally appeared in The World Bank Group. Taking on Inequality, Poverty and Shared Prosperity 2016. Copyright © 2016 The World Bank. ~6). Uganda has a gross national income per capita of $630 (see Table 2.1) and despite recent increases in THE/GDP (7.2% vs. 17.10% in the United States), many healthcare challenges exist (life expectancy 56 years), especially with regard to anesthesia and surgery.[76,156]

The first recorded anesthetic in Uganda was a cesarean delivery in 1879 with the use of banana wine as the anesthetic.[157] The first modern anesthetic (chloroform) was given by Sir Albert Cook in 1897.[158]

Anesthesia was initially most commonly given by surgeons. Theater attendants and medical assistants were also trained on the job to administer anesthesia. In the 1970s and early 1980s, a 2-year anesthesia diploma program (anesthetic assistants) was created. In 1985, during a meeting of the Commonwealth Health Ministers of the East, Central, and Southern Africa region, it was established that a medical background was vital for anesthesia provider training. This resulted in abolishment of the “anesthetic assistant” programs and creation of a 2-year diploma (anesthetic officers) in 1986 that required a diploma in clinical medicine, nursing, or midwifery as a prerequisite.

Until the 1980s, training of Ugandan physician anesthesiologists was primarily foreign-based, and due to political turmoil, few returned to Uganda to practice. One anesthesiologist returned in the mid-1970s and started the Department of Anesthesia at Mulago Hospital (Kampala, Uganda). Together, with an Australian anesthesiologist, they established a 1-year Diploma in Anesthesia in 1985, and the following year the Anesthesia Master of Medicine (MMED), a 3-year residency program at the Makerere University Medical School. In 1990, with a total of 4 physician anesthesiologists and roughly 100 nonphysician anesthetists in the country, the Uganda Society of Anesthetists was founded.

Today there are two physician MMED and three nonphysician diploma programs in Uganda. A new nonphysician, 4-year Bachelor’s in Anesthesia program was also started in 2017. Each institution awards a qualification to its graduates, as currently there is no accrediting body for anesthesia in Uganda. Regionally, the College of Anesthesiologists for East, Central, and Southern Africa (CANECSA) was founded in 2014 but has not started accreditations.

From 2000–18, the number of physician anesthesiologists in Uganda has increased from less than 10 to over 80, with the majority working near the capital (Kampala). Nonphysician anesthetists outnumber the physician anesthesiologists by almost 6 times and are distributed widely throughout the country where they usually practice without supervision or team support. Despite increasing numbers in recent years, vast shortages in the anesthesia workforce limit access to care throughout the country. Over the past decade, about 10% of physician anesthesiologists have moved to other countries in Africa. This brain drain has been reported in many other countries, including Francophone Africa under the Cotonou program, where brain drain was reported at nearly 18%.[108] In addition to this external brain drain (i.e., emigrating to another country), internal brain drain (e.g., leaving the public sector for private practice, staying in urban centers, or leaving the field of anesthesiology) is also a significant challenge throughout the region. These moves are motivated by economic incentives and political changes.

In 2007, the Ugandan health ministry established health sub-districts in each county (about 150 countrywide), each with an operating theater for provision of emergency obstetric and surgical care. Unfortunately, they were ill-equipped, and many are nonfunctional. None of the 33 district hospitals have a physician anesthesiologist (despite position vacancies), and only 4 of 13 regional referral hospitals have an anesthesiologist on staff. There are currently 25 anesthesiologists in the national referral hospital together with the teaching faculty in the two MMED programs. All other physician anesthesiologists in Uganda are working in private hospitals and universities.

Safety standards in Uganda are based mainly on WFSA guidelines, however, these are not strictly enforced.[3] Compliance rates with the WHO Surgical Safety Checklist are low as is capacity to comply with the checklist requirements. A survey of utilization of the checklist in major East African hospitals showed variable compliance (19% to 65%).[94]

Administration of ether anesthesia with the Epstein, Macintosh, Oxford (EMO) vaporizer is still used in remote locations of Uganda, although its use has declined significantly in recent years. Throughout the country there are a wide range of configurations ranging from EMO drawover setups to modern anesthesia machines for cardiac bypass surgery (see Fig. 2.14). Limitations in reliable power, disposables, and oxygen are among the many infrastructure challenges that affect daily anesthesia care in almost all locations. Even with monitoring, there are significant differences in what is available ranging from a basic stethoscope and blood pressure cuff to monitors allowing for invasive monitoring. In recent years, the scope of practice has expanded as more providers are completing subspecialty training abroad (e.g., pediatrics, cardiac, obstetrics, critical care, and regional) and returning to practice and teach locally.

Besides the nearly universal problem of remuneration, the greatest challenge for anesthesia in Uganda is the massive imbalance between the workforce and the workload. This imbalance coupled with ill-equipped workplaces makes the provision of safe care difficult, and provider burnout is commonplace.

South Africa (Hyla Kluyts)

South Africa is home to approximately 56.5 million people of diverse ethnicity and culture.[159] Since the first democratic election in 1994 and the adoption of the South African Constitution in 1996, the country has been struggling to address its inequalities. In health care, there have been successes such as the decreasing incidence of HIV infections and increasing life expectancy (from 55.2 years in 2002 to 62.4 years in 2016). South Africa has a gross national income per capita of $5,480 (upper middle-income country), yet approximately 19% of the population live below the World Bank poverty line (US$1.90 per day) and only 17% of the population have private medical insurance.[76] The proportion of the population living below the extreme poverty line is much higher than that of many other middle-income countries. A recent collaborative report by the World Bank denotes South Africa as "one of the most unequal countries in the world."[160] The South African Department of Health is working toward universal health coverage and a draft National Health Insurance Bill was published in June 2018.[160a]

Ether was first used for dental extractions in Cape Town in April 1847, and the first major operation under anesthesia was performed in June of the same year. The first specialist anesthetist, British-born and -trained Dr. Bampfylde Daniel, was appointed at Johannesburg Hospital in 1907. The South African Society of Anaesthesiologists (SASA) was founded in 1943 and was a founding member of the WFSA in 1955. SASA published its first Practice Guidelines in 1987, with five subsequent revisions, including 2012 and 2018 revisions that adhere to the WHO-WFSA International Standards on the Practice of Safe Anaesthesia.[161]

Physicians are trained and accredited to provide anesthesia care as general practitioners or specialists. General practitioners are registered as independent practitioners after completing 6 years of undergraduate study and 3 years of supervised training as interns and subsequent community-service medical officers. A general practitioner can obtain a Diploma in Anaesthesia after 6 months of full-time supervised practice in an accredited institution. Specialists can register as such after completing a 4-year postgraduate training period, completing of a research project, and successfully passing the South African College of Anaesthetists' final Fellowship examination.

The Health Professionals Council of South Africa (HPCSA) certifies medical professionals and is the accreditation body for anesthesia training. Eight university departments across the country are responsible for the academic input and implementation of training pathways, whereas the Provincial Departments of Health dictate the number of posts within these training pathways. The curricula are determined by the Colleges of Medicine of South Africa, which also is responsible for assessments and examinations.

Anesthesia providers in South Africa consist of independent practitioners (general practitioners or specialists in both private and public sectors) supplemented by interns, community service medical officers, specialist trainees, and foreign physicians who do not qualify for registration as independent practitioners and must work under supervision in the public sector. Anesthetists in private practice in South Africa are not hospital based and travel between hospitals according to demand from surgical colleagues. The SASA therefore plays a significant role in the private sector as a representative body for clinician interaction with other stakeholders. In contrast, all public sector anesthetists are employed by the provincial Departments of Health at specific hospitals.

The already limited specialist anesthesia workforce is also unequally distributed between the private and the public sector, and between rural and urban areas in South Africa. For example, approximately 1800 specialist anesthesiologists were registered with the HPCSA in 2017, of which around 1100 specialists are SASA members, and of these, 790 work in the private sector. Roughly 9 million patients are insured and cared for in the private sector.[161] Unsatisfactory working conditions and remuneration are the most commonly quoted reasons for anaesthetists leaving the public sector for the private sector after registering as specialists.

There is limited information available regarding the number, distribution and training of non-specialist anesthesia providers in South Africa. The number of non-specialists choosing full-time anesthesia practice as a career is relatively low and likely does not significantly address the lack of anesthesia services available to the population in either sectors of the healthcare system. At best, the estimated total number of anesthesia providers per 100,000 of the population is half of the minimum required for safe care. No non-physicians provide anesthesia in South Africa. Attempts have been made to train more doctors and to recruit doctors to areas of need (e.g., implementation of rural allowance payments). Anesthetists also form part of the District Clinical Specialist Teams alongside the family physicians, primary healthcare nurses, and specialist obstetricians. These teams were created to improve maternal and neonatal mortality and morbidity at a district level, though anesthesia posts within these teams remain largely unfilled and are not considered mandatory for "minimal team" standards.

Access is a major barrier because of the country's geography and distribution of available resources. About one third of the poorest population in South Africa have to travel at least 20 km to the nearest hospital.[160] Often these level 1 facilities provide obstetric surgery services but not surgical services for the bellwether procedures largely because of the failure to recognize basic surgical care as a public health issue.

Information on anesthesia-related outcomes is not available on a national level, but some useful data are obtained through reports from the National Committee for the Confidential Enquiry into Maternal Deaths.[71] Surgical outcomes for South Africa and Africa have been reported following recent multicenter studies.[65] Regulation of healthcare expenditure, improving access to essential surgical care in rural parts of the country, and increasing data perioperative care and on resource distribution will be critical to improving anesthesia and surgical care in South Africa.

NORTH AMERICA

North American countries have widely different economic, political, and healthcare systems. This section describes examples from two HICs (Canada and the United States) and one middle-income country (Mexico). These two HICs have extremely different models of health care as well as anesthesia services. Canada has a predominantly physician-based system and universal health coverage, while the United States is split nearly equally between physician and nonphysician providers. Mexico is physician-based, but with a novel and controversial rural physician anesthesia program. Haiti is the only LIC in North America and suffers from shortages of healthcare providers that are orders of magnitude worse than other countries in the region. There are fewer than 100 anesthesiologists for the country's population of 10.85 million, and most only work in the capital city. In 1998 Médecins Sans Frontières began a nurse anesthetist training program in collaboration with the Ministry of Public Health and Population (independent from The Haitian Medical Association and the Haitian Society of Anesthesiologists), though numbers of nurse anesthetists remain critically low.[100,162]

Canada (Tyler Law)

The first reported anesthetic in Canada was administered in 1847, just after Morton's demonstration in Boston, as a result of the ship carrying the news from Boston to London, via Halifax.[163] The first formal anesthetic training program began in 1910 in Toronto, and anesthesia as a profession became formalized with the creation of the Canadian Anesthesiologists Association in 1943.[164]

PAPs undertake a 5-year specialist anesthesia residency directly from medical school, or through the International Medical Graduate program designed to train practicing physicians from other countries to national standards. This training focuses on the progressive, successful demonstration of task competency (termed entrustable professional activities [EPAs]), rather than time-based rotation training. The EPAs are consistent across residency programs, and residents receive frequent feedback on their performance. Residents must demonstrate competency in EPAs before advancing to the next phase of training.[165,166]

The Royal College of Physicians and Surgeons of Canada sets accreditation standards and required competencies for anesthesiologists in conjunction with the training programs. In conjunction with EPAs, the Royal College certifies a national examination with written and oral components that tests knowledge, application of knowledge, and clinical judgment. Standardized simulation scenarios are being gradually introduced as a component of specialty certification.

The count of physician anesthesiologists in Canada has increased significantly from 2500 in 2005 to 3300 in 2018, resulting in a provider density of 9 anesthesiologists per 100,000 population. In Canada, anesthetics are largely given by specialist physicians, with several additional healthcare provider cadres also administering anesthesia care. Graduates of the two-year Family Medicine residency may opt to take a 1-year "added skill" training program in anesthesia. They practice anesthesia independently for less acute patients and procedures, often in a community or low-volume setting.

A small number of dentists administer both general anesthesia and sedation for dental procedures, typically in ambulatory settings in the clinic or hospital. A 3-year training program undertaken after the completion of dental school enables them to care for ASA physical classification 1, 2, and stable 3 patients.[167] The anesthesia care team also includes anesthesia assistants, who undertake a prescribed educational program (most often 1 year in duration) and provide technical assistance with equipment and perform clinical tasks (such as intubation or intraoperative medical management) under the supervision of an anesthesiologist.

Guidelines for anesthesia practice have been established by the Canadian Anesthesiologists Association and are regularly updated for the core elements of anesthesia practice in Canada, and guidelines from the ASA and other international societies are commonly referenced. Notable elements of recent guidelines include encouraging the use of a structured handover protocol, and requiring capnography monitoring for moderate or deeper sedation.[168]

Most anesthesiologists practice in academic health centers and community hospitals.[169] The costs of most surgical, anesthetic, and postoperative inpatient care services are covered under provincially administered public health insurance schemes. Only 0.7% of private health spending is directed toward physicians, so the market for private anesthetic services is small and usually restricted to services not covered under public plans, such as dental and cosmetic procedures.[170]

Despite universal health coverage and a relatively large number of anesthesia providers, Canada still faces several challenges relevant to anesthesia and surgical care. Canada is the second largest country (by land mass) in the world, and while much of the population is geographically clustered, rural areas suffer from the lack of consistent access to health care, particularly lack of access to specialists including anesthesiologists. Many northern communities have sizable First Nations (indigenous) populations, who are disproportionately underserved. Similar to the United States, tension among anesthesia provider roles is an ongoing issue.

Mexico (Gerardo Prieto)

The Aztec and Maya were among the earliest anesthetists in Mexico and known for using herbal beverages to produce analgesia, with adjuncts such as rattlesnake fangs, leeches, porcupine needles, and the maguey needles to produce local numbness.[171] The Maya witch doctors were divided into specialty groups according to the diseases that they either cured or produced. The first mention is a witch doctor who produced *"sleepiness"* called Ah Pul Uenel, who used plants that produce hallucinations and nervous system stimulants. Also mentioned is Pul-Yahob who treated wounds and pain with different rituals, plants, and animals.

As in many countries, surgeons provided the first contemporary anesthetics in Mexico. The first ether anesthesia in Mexico was performed in 1847 by the military surgeons E. H. Barton and Pedro Vander Linden for a cannon ball wound amputation, during the U.S. Intervention War in Veracruz.[172] In 1852, Dr. Pablo Martinez Del Rio used ether in an obstetric patient during a session of the Medical Society. Dr. Ramos Alfaro is attributed as the founder of Mexican anesthesia with his introduction of chloroform anesthesia in 1852.[173] In 1900, Dr. Juan Ramon Pardo Galindo performed the first spinal anesthetic in Mexico and Latin America. In 1934, the first formal diploma in anesthesiology (DA) was awarded, and The Mexican Society of Anesthesiology (Sociedad Mexicana de Anestesistas) was formed. In 1957 the first contemporary anesthesia residency programs were formed, and in 1973 the Mexican Council of Anesthesia was registered and was active until 2013 when it became the National Council of Certification in Anesthesia (CNCA).

In Mexico, anesthesia training programs are 3 to 4 years in duration after medical school and authorized by a university and a recognized institute of medicine. Once this program is completed, trainees must pass the National Council of Certification in Anesthesia to receive a 5-year license. Mexico has subspecialty training in cardiac, pediatric, neuro, obstetrics and gynecology, and trauma anesthesia.

Mexico City is one of the most populated cities in the world, absorbing an estimated 70% of all Mexican anesthesiologists in a 300-mile radius. Many factors make medical access extremely difficult for large parts of the population, such as the broad geographic distribution of the Mexican population, rural indigenous tribes speaking different dialects, low per-capita income (gross national income per capita US$16,176), and the concentration of healthcare resources in urban areas.

In the wake of Mexico's economic crisis in 1994, the country was forced to evaluate how to improve access for the most impoverished and marginalized parts of the population. The program that emerged was called PROGRESA (Programa de Educación, Salud, y Alimenación) and was designed to alleviate poverty by developing human capital. Part of this program aimed to fill the shortage of specialists working in rural environments. The government and Mexican Social Security Institute established the idea of training "rural specialists" in surgery, obstetrics, pediatrics, and anesthesiology. Medical school graduates who did not pass the national examinations for admission to residency programs were enrolled and trained to work in rural areas for as little as 6 months to 2 years (often with limited educational resources). In many instances these providers migrated to the larger cities or towns. Approximately 500 graduates have been trained by this program, and in 2016 the government ordered the National Council of Certification in Anesthesia to allow rural anesthesia graduates to take the national examination. If these providers pass, they are given a certificate for rural practice only. If they do not pass the written examination in three attempts, they are given the opportunity to complete a practical examination. The efficacy of this training and impact of the program overall remain controversial.

In Mexico there are approximately 13,000 certified anesthesia practitioners for 128 million people (7 per 100,000 population), with 70% located in central Mexico. Approximately 85% of surgical procedures are performed in Government Social Hospitals and 15% in private practice. The Mexican Social Security Institute estimated that 2.5 million procedures were performed in 2015, and when including all the government hospitals and private practices, it is estimated that well over 5 million anesthetic procedures are performed each year.[8]

Mexico faces significant challenges providing access to anesthesia services outside of a few urban settings. In 2012, it was estimated that 21.5% of the population (~25 million people) lacked access to health services. The country has relatively sufficient anesthesia training capacity and increasing numbers of specialist anesthesiologists, yet provider maldistribution is currently the dominant factor limiting access. Additional challenges facing the anesthesia community in Mexico include provider burnout, addiction, and limited data on anesthesia safety.

A number of anesthesia patient safety initiatives are ongoing in Mexico, including legal mandates (the "Norma Oficial Mexicana de Anestesiologia 006") that specify practice requirements for anesthesiologists and hospitals. Success of these efforts will be contingent on addressing each of the challenges discussed previously.

United States (Ronald D. Miller and Adrian W. Gelb)

Anesthesia slowly gained acceptance as a medical specialty in the United States after the initial ether demonstrations by Morton in 1846. It was taught irregularly and informally throughout the early 1900s as a task performed by medical students, interns, or nurses. A large proportion of anesthesia in the United States was provided by nurses, even though the designation of Certified Registered Nurse Anesthetist (CRNA) was not formalized until 1956.

The first anesthesia society in the United States was the Long Island Society of Anesthetists, established in 1905, and the first department of anesthesia and residency program was established by Ralph Waters at the University of Wisconsin in 1927. This program produced several key leaders in anesthesiology directly (e.g., Cullen, Apgar, and Rovenstein) and indirectly (Stoelting, Miller) (Fig. 2.16). The American Board of Anesthesia (ABA) was formed in 1938 to serve as the certification body for anesthesiologists. Anesthesia was recognized as a specialty by the American Medical Association (AMA) in 1940, and the ASA was established in its current form in 1945.[163]

Physician anesthesiologists in the United States must obtain a medical degree (Doctor of Medicine or Doctor of Osteopathic Medicine) followed by specialty (residency) training in anesthesia. An undergraduate bachelor's degree (3-4 years) is required before entering medical school.[174] Residency in anesthesia lasts 4 years: 1 year of general medical internship and 3 years of anesthesia and perioperative medicine training. Residents rotate through the operating room (including subspecialty cases), pain medicine, and at least 4 months of intensive care. Residency training requirements are prescribed by the Accreditation Council for Graduate Medical Education (ACGME). Graduates of an ACGME-approved program are eligible for ABA certification after passing two written examinations (BASIC and ADVANCED), a standardized oral examination, and an objective structured clinical examination. Board

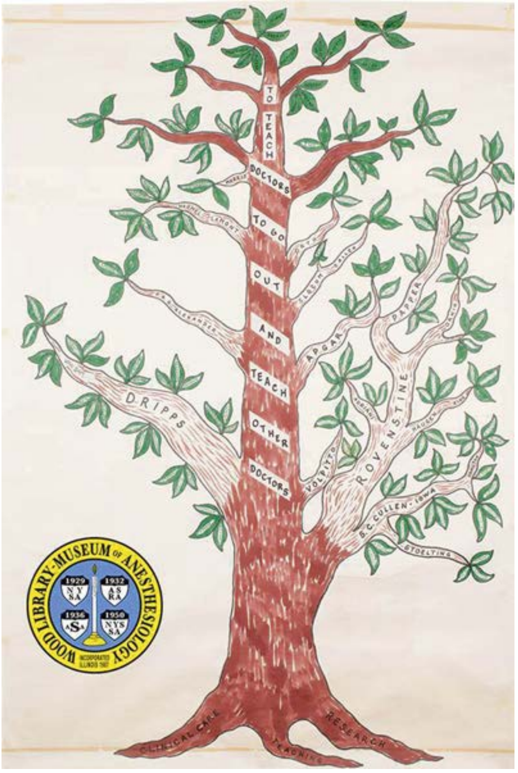

Fig. 2.16 The Aqualumni tree (created by Lucien E. Morris, Ralph M., and Jean P. Morris) depicting names of chairpersons or heads of academic anesthesia centers that came from the lineage of the world's first postgraduate academic residency program in anesthesiology led by Dr. Ralph Waters at the University of Wisconsin. (Copyright © 2018 https://www.woodlibrarymuseum.org. Image reproduced courtesy of the Wood Library-Museum of Anesthesiology, Schaumburg, IL.)

certification is a prerequisite for most hospital-based jobs in anesthesia.

Nurses with at least 1 year of practice in critical care are eligible to train as CRNAs. Training ranges from 24 to 42 months and confers a master's-level degree or higher. Training guidelines are specified by the Council on Accreditation of Nurse Anesthesia Educational Programs and mandate at least 465 hours of classroom education, exposure to a minimum of 600 clinical cases, and 2000 clinical hours.[175] Like physicians, CRNAs who complete an accredited program may take the National Certification Exam administered by the National Board of Certification and Recertification for Nurse Anesthetists.

Certified Anesthesiologist Assistants are a relatively new anesthesia provider group in the United States. Although the first training program opened in 1969 in an attempt to address significant provider shortages that existed in the United States at that time, the cadre has been relatively slow to increase numbers. Certified Anesthesiologist Assistants complete an undergraduate degree with pre-medical studies and then enter a 2.5-year anesthesia training program that is done in collaboration with an anesthesiology department. They conduct anesthesia as directed by a supervising anesthesiologist, and work in close collaboration with the anesthesiologist who leads the care team.

Physician anesthesiologists in the United States are involved in all aspects of perioperative care, including preoperative optimization in outpatient clinics, management of acute postoperative pain, obstetrical anesthesia services, and responding to traumas and inpatient emergencies. They also frequently manage ICUs after completing subspecialty training in critical care.

There are approximately 50,000 physician anesthesiologists, and 50,000 registered CRNAs in the United States, for a combined density of approximately 31 providers per 100,000 people.[176,177] The composition of the anesthesia care team may include from physician anesthesiologists only, to physician anesthesiologists supervising either CRNAs or anesthesia assistants, to CRNA-only models. Federal regulations mandate physician supervision of CRNAs, but 17 states have opted out of this requirement following the introduction of legislation in 2001.[178] Among the 17 states that have opted out, 14 require some degree of physician oversight (not necessarily by an anesthesiologist) and only 3 allow completely independent CRNA practice.

While it is unproven if nonphysician cadres in the United States increase access to anesthesia or provide care with different quality outcomes, data demonstrates that CRNAs are more likely to practice in rural locations and perform more anesthetics under sedation (i.e., MAC) than physician anesthesiologists.[179,180]

Although overall provider density is high in the United States, there is stark geographic maldistribution with providers concentrated in urban areas. Many less populated areas report significant surgical delays due to the lack of anesthesiologists.[95] Access to subspecialists is also limited. For example, nearly one third of the United States pediatric population lives more than 50 miles from the nearest pediatric anesthesiologist.[181]

Maternal mortality has increased in the United States in the last 10 years, though anesthetic-related maternal mortality has declined.[182] The causes are multifactorial, may be attributable to the changing risk profile of obstetric patients, and pose a dynamic challenge to anesthetists.

The high costs of care and incomplete financial coverage (insurance) are two additional, evolving challenges in the United States with significant repercussions and relevance for anesthesia care. Lastly, significant ongoing debate exists over anesthesia provider roles.

EUROPE

Although Europe and the European Union (EU) may appear as one entity, the countries represented are diverse with regard to population, economic situation, culture, and political leadership. Similar diversity is also seen for the training and organization of anesthesiology services in these countries. The official EU title of the specialty is "Anaesthetics," and the only EU training requirement is that its duration should be 3 years.[183] In reality, the duration of training is anything from 3 to 7 years, and the involvement in anesthesia, intensive care, pain, and critical emergency medicine varies to a great extent among countries.[184] The European Section and Board of Anaesthesiology (EBA) of the European Union of Medical Specialists (UEMS) is the political branch of European anesthesiology. The UEMS aims to promote and harmonize the highest level of training of the medical specialists, medical practice, and health care within the EU, and to promote free movement of specialist medical doctors within the EU. The EBA/UEMS has published training guidelines to encourage countries to aim for an agreed standard.[185] In cooperation with the scientific branch of European anesthesiology, the European Society of Anaesthesiology (ESA), the UEMS offers the European Diploma of Anaesthesia and Intensive Care (EDAIC). Another building block for European Anaesthesiology is the Helsinki Declaration on Patient Safety in Anaesthesiology, which was introduced in 2010.[186] In the following paragraphs we describe the situation in two countries—Romania, a middle-income EU member state with a population of 19.7 million and physician-only service, and Norway, a high-income, non-EU member state with a population of 5.2 million and where the team approach is the anesthesia service model.

Norway (Jannicke Mellin-Olsen)

In Norway, the first ether anesthetic was provided at Rikshospitalet (the National Hospital) in Oslo on March 4, 1847.[187] In April, the first ether inhalation for labor followed. At that time, younger surgeons and GPs and later nurses were in charge of anesthesia delivery. In the 1930s two surgeons (Carl Semb and Johan Holst) facilitated anesthesia training opportunities for physicians Otto Mollestad and Ivar Lund in London and Boston (Massachusetts General Hospital), respectively. Dr. Mollestad was hired without salary in 1939, and as the first consultant in anesthesiology in 1947.

The Norwegian Society of Anaesthesiology was founded in January 1949 with only seven members. The founding members faced significant difficulties promoting the specialty, but the anesthesia nurses welcomed physician involvement and leadership.

Physician specialty training is 5 years. There is no final examination, but there are course exams and procedure checklists, in addition to continuous individual assessment. Trainees are encouraged to take exams for the EDAIC. The nurse anesthetist training program is 1.5 years after 3 years of nursing education. Both physician anesthesiologists and nurse anesthetists are accredited by the Directorate of Health.

The first guidelines that described the scope of practice and dynamics of the anesthesia team were authored by both physicians and nurses in 1993.[188,189] It was agreed that anesthesiology is a medical specialty. A physician is responsible for all anesthetic procedures, although nurses are allowed to provide anesthesia for ASA physical classification 1 and 2 adults with indirect supervision. At induction and emergence, there must always be two anesthesia-trained persons immediately available. The "flexible anesthesia team" usually consists of one physician and one nurse.

Anesthesiology is an attractive and prestigious specialty in Norway (second to thoracic and neurosurgery only), and works closely with almost all other hospital specialists, including the surgeons.[190] In contrast to many other countries, anesthesiologists in Norway are highly respected by the general public. This is partly due to increased visibility, as anesthesiologists provide leadership not only in anesthesia, but also perioperative medicine, pain management, intensive care, and critical emergency medicine (including prehospital services). There are currently 1329 physician anesthesia providers (25.5 per 100,000 population) and 2000 nurse anesthesia providers.[100] Anesthesiology is among the medical specialties with the lowest female representation (30%). As Norway has generous paid maternity and paternity leave, the norm is that both sexes stay in the profession and work full-time.

Health care in Norway benefits from the country's economic prosperity, robust public programs, and emphasis on patient safety. The Norwegian Society of Anaesthesiology was among the first signatories of the Helsinki Declaration on Patient Safety in Anaesthesiology, and the WHO Surgical Safety Checklist is distributed and used nationwide. Norwegian health care is funded primarily by the government. Hospital care is free of charge for the patient, as are medication costs once a specified amount is surpassed. Private hospitals exist but provide mostly elective surgery.

Current challenges facing the anesthesia community in Norway include concerns about costs and quality, although in general, hospitals are well equipped. In recent years there has been increasing frequency of medicine shortages, mostly due to the lack of domestic production and export policies of drug companies that can have adverse safety consequences.

Romania (Daniela Filipescu)

The first anesthetic in Romania (ether for a limb amputation) was documented in the journal "TemesvarerWochenblatt" and took place on February 13, 1847.[190a] The world's first-ever use of opioids for intrathecal anesthesia was presented by a Romanian in Paris in 1901.[191] Thoma Ionescu further developed the technique and published the first textbook of intrathecal anesthesia—*La rachianesthésie générale.*[191,192]

The first anesthesia training course in Romania was held in 1951, and a formal 1-year training course began in 1959, after the recognition of Anesthesia and Intensive Care Medicine (AICM) as an independent medical specialty.[190a] The first ICU was instituted in 1958, but it was only in 1972 that AICM departments were formally introduced in the Romanian medical health system.

The first AICM study group was founded by Zorel Filipescu in 1958. The study group was included later as part of the Romanian Society of Surgery and separated as an independent Romanian Society of Anaesthesiology and Intensive Care (RSAIC) in 1972. The RSAIC joined the WFSA the same year.

In Romania, specialist physicians are the only formal anesthesia provider cadre. After graduating from medical school (MD), physicians may enter specialty training after passing a written national examination. The number of places for each specialty is decided by the Ministry of Health, and admission to a specialty depends on candidate preference and performance on the written examination. Usually, AICM is among the top specialties chosen for training due to the wide range of opportunities to work abroad. The Romanian MD and specialist diplomas are automatically recognized in EU countries.

The AICM specialty training is five years and includes two years in intensive care medicine. Romania endorsed the competency-based European Board of Anaesthesiology Curriculum for Anaesthesiology, Intensive Care, and Pain Therapy, but this has been only partially implemented. For obtaining the specialist certification, written and oral examinations must be taken at the end of the training period. Romania adopted the EDAIC Part I examination organized by the ESA as the national written examination since 2010. All physicians practicing in Romania have to be evaluated and re-licensed based on a minimum 200 continuing medical education (CME) credits accumulated every 5 years. There are no specialized anesthesia nursing cadres recognized in Romania, but general nurses may apply for posts in AICM departments where they are trained locally for the job.

An estimated 1400 anesthesiologists are currently practicing in Romania, and approximately 180 trainees are entering the specialty each year. Trainees are distributed to 12 academic centers in the country, although most trainees are taught in the five largest academic centers. The majority of anesthesiologists work in public hospitals though a small number work in private centers and some in both.

Safety in AICM is promoted by the RSAIC, which signed the Helsinki Declaration on Patient Safety in Anaesthesiology, endorsed the WHO checklists, the ESA clinical guidelines, and launched national guidelines. Despite this attention to patient safety, the European Surgical Outcomes Study (EuSOS), which included 17 hospitals and 1298 patients from Romania, demonstrated a higher postoperative mortality (6.8%) after nonemergent general surgery in Romania than the European mean value (4%).[193] Subsequently, a national program for critical care was implemented, and the more recent International Surgical Outcomes Study (ISOS), which included 1875 patients from 26 Romanian hospitals, demonstrated improved outcomes.[194]

The anesthesia community in Romania faces several challenges. A key challenge limiting anesthesia access in Romania is the shortage of providers (anesthesiologists and trained AICM nurses) as well as equipment technicians. Reasons for these shortages include internal and external brain drain (mostly to Western Europe).[195] Workforce shortages particularly affect ICU activities as well as operating theaters where a provider may be assigned multiple rooms simultaneously. Another barrier to scaling the workforce is the lack of a nationally standardized AICM nurse curriculum and training. Additional challenges routinely encountered in Romania include the uneven distribution of specialists and equipment as well as significant infrastructure limitations and drug shortages. For example, ultrasound and certain essential medications (e.g., tranexamic acid, amiodarone) are not universally available. Although the practice of AICM includes perioperative care, there are no formal anesthesia preoperative evaluation or pain therapy centers organized in the public hospitals in Romania. A final and significant challenge facing anesthesia providers is the unavailability of adequate malpractice coverage options which has resulted in defensive medical practices.

Despite the current challenges, the AICM is one of the most dynamic specialties in Romania, with a tremendous development led by dedicated RSAIC leadership.

ASIA AND THE MIDDLE EAST

Asia is the largest continent with a population of 4.43 billion. There is a wide socioeconomic variation among the countries with the GDP PPP (at purchasing power parity) per capita income ranging from 1944 International dollars for Afghanistan to 127,480 for countries like Qatar.[76] Anesthesia services also vary widely. Anesthetic societies are functional in the majority of the countries and a number of societies located in the same geographic regions have voluntarily come together to form regional societies. The officially recognized regional sections of the WFSA in Asia are the Pan Arab Federation of Societies of Anesthesia, Intensive Care and Pain Management (PAFSA) founded in 1884, Confederation of ASEAN Societies of Anaesthesiologists (CASA) as part of the Asian Australasian Regional Section founded in the 1970s, and the South Asian Association of Regional Co-operation—Association of Anaesthesiologists, which came into existence in 1991.

India (Bala Krishnan Kanni)

The first administration of ether anesthesia in India was on March 22, 1847, and the first chloroform anesthesia was administered on January 12, 1848. Chloroform and ether continued to be used until the mid-1950s in many hospitals. Halothane was introduced in 1960 and isoflurane in 1992.[196] Regional anesthesia (with cocaine) was first reported in 1894 and spinal anesthesia with hyperbaric Stovaine (amylocaine) was reported in 1908. In 1935, the first Boyle's apparatus machine arrived in India, and the same year the first oxygen plants were established in Calcutta (Kolkata). The Indian Society of Anesthesia (ISA) was established in 1947. The first official Journal of the ISA was published in July 1953, and in 1956 the ISA joined the WFSA as a founding member.

Formal anesthesia training for undergraduates in India officially started in 1906, followed by diploma (1946) and MD/MS degree programs (1955) in anesthesia. The National Academy of Medical Sciences started Diplomate of National Board of Examinations in 1970 followed by PhD programs in anesthesia. Today, all anesthesiologists in India are required to undergo one of three training pathways prior to independent practice. These pathways take place after completing 4 years of medical school (Bachelor of Medicine, Bachelor of Surgery–MBBS) and 1 year as an intern or "house surgeon." The first training pathway requires physicians to complete 3 years of postgraduate anesthesia training with a dissertation at a university hospital. The second potential pathway is called the Diplomate of the National Board (DNB) and requires 3 years of training as well as a dissertation at a hospital approved by the National Board of Examinations. Physicians can also pursue a 2-year postgraduate diploma program at a university hospital without dissertation. Holders of this latter postgraduate Diploma in Anesthesia often practice with supervision of more senior anesthesiologists. There are no nurse anesthetists in India, and the total number of anesthesiologists in the country (population 1.34 billion) is approximately 25,000 (see Table 2.3).

There have been several attempts to train non-anesthesiologists as stop-gaps for the ongoing workforce crisis. In 2002 the Indian government started a short-term training program for doctors but this could not be sustained due to problems in implementation and lack of support from the government. One ongoing program provides 6 months of training to physicians post-medical school to carry out cesarean sections and lifesaving anesthetic skills for emergency obstetric care in rural facilities where no anesthesiologist exists.[197,198] This program is controversial and not universally supported. India also trains Operation Theatre Technologists (OTT) or Assistants who may undergo a 3-year diploma or 6-month to 1-year training program straight from secondary school. These cadres have limited scopes of practice (e.g., can place IVs or administer medications) and must practice under direct supervision of anesthesiologists. Although the OTTs are not permitted by the ISA to perform tasks such as intubation or neuraxial anesthesia, there are significant concerns that such practice takes place in some centers.

In addition to shortages in number, the anesthesia workforce in India also suffers from inequitable distribution, with a disproportionate number of providers in urban areas. Because anesthesiologists in India are also responsible for many services outside of the operating theaters (e.g., preoperative preparation, postoperative care, and critical care), these services are also frequently unavailable.

The ISA is actively engaged in several activities to promote anesthesia safety throughout India. With initial financial assistance from WFSA, the ISA started a CME program for rural anesthetists to update knowledge and techniques. The ISA endorses the WFSA and WHO guidelines for minimum monitoring standards, the WHO Safe Surgery Checklist, as well as many other anesthesia safety practices (e.g., color coding of drugs, syringe labelling, machine checks, and appropriate records of anesthetic care). Significant efforts have also been made to educate the public about anesthesia and its safety by holding public education programs.[199]

Although safe anesthesia services are available in many institutions both public and private throughout India, access to modern equipment and facilities are not universal. Much like providers, anesthesia infrastructure is also concentrated in urban areas. Anesthesia subspecialties such as neuro, cardiac, pain, pediatrics, and obstetrics are available in most urban hospitals but few rural facilities.[200] As a result, many rural facilities lack capacity for safe anesthesia care. Additional challenges limiting access to safe anesthesia care in India include poverty, distance to care, social and cultural barriers, and comorbidity.

Lebanon and The Middle East (Patricia Yazbeck)

The oldest medical writings in the region were found in cuneiform tablets and Eber's papyrus in Mesopotamia and the Nile valley, describing herbal treatments like Belladonna, Cannabis, and Mandragora. Phoenicians also obtained artificial sleep by using calming herbs, opium poppy, and juniper leaves. In the Middle Ages, prominent Arab scholars (Avicenna, Al Razi, Ibn Al Quff, Al Baghdadi, and others) made important contributions to the field of medicine.

In 1835, the first Arab medical school in the Middle East was established by Dr. Clot in Kasr-Al-Aini Hospital, in Cairo. Graduates practiced in all the large cities of the region. In 1860, American, French, and British powers intervened in the region and with the inflow of missionaries, more medical schools and hospitals were established. In Lebanon, the Syrian Protestant College (American University of Beirut) was founded by American missionaries in 1886 while the French Medical School (St Joseph University) was founded by the French Jesuits in 1883. The first use of inhalational anesthesia occurred in 1865 by Dr. George Post, an American missionary surgeon who administered "kulfera" (chloroform) in the village of Abeih-Lebanon. Dr. Post is considered the pioneer of modern anesthesia in the Middle East (Fig. 2.17).[201]

At the end of WWI, the practice of anesthesia still depended on foreign surgeons, and on local and foreign nurses or technicians, administering ether or chloroform. But the beginning of oil production in the region contributed to economic improvement and led to the foundation of many faculties of medicine in Syria, Sudan, and Iraq. After 1950, Middle Eastern countries established fully independent anesthesia departments with their own structure, staff, residency training, research, and certification by international academic institutions. In addition, in the 1960s and 1970s, many countries founded their own national anesthesia societies and in 1985 a Pan Arab Society of Anesthesia, regional section of the WFSA, was founded.

Anesthesia departments in the Middle Eastern countries are staffed by highly qualified faculty certified either by the Arab Board or by foreign academic bodies, such as the American, French, or European Boards of Anesthesiology or by the RCoA.

A residency program of 4 years in a recognized center may be followed by 1 or 2 years of fellowship in pain management, critical care, obstetric anesthesia, cardiopulmonary anesthesia, or others as recognized by the national anesthesia societies, which also track CME.

Anesthesia is routinely administered by a qualified anesthesiologist. Trainee anesthesiologists or anesthesia nurses can administer anesthesia under the supervision of a qualified anesthesiologist. The density of physician anesthesia providers per 100,000 population is less than three in Morocco, Syria, and Iraq, and less than one in Yemen and Sudan while it ranges from six to more than 10 in countries like Egypt, Oman, Jordan, Lebanon, United Arab Emirates, and Kuwait.

The responsibilities of the anesthesiologist include preoperative assessment and preparation, premedication, as well as staffing PACUs and ICUs. Anesthesia is administered in the operating room, delivery suite, radiology department, and as ambulatory anesthesia. In addition, acute or chronic pain management is becoming routinely practiced. Departments and societies of anesthesiology in the Middle Eastern countries are responsible for setting practice guidelines, matching the standards approved by international societies, such as the American, French, or European Societies of Anesthesiologists. Anesthetic machines, monitoring equipment, and agents adhere to the international standards.

The major key challenges and barriers to safe anesthesia in the region are the consequence of the recent turmoil occurring in many Middle Eastern countries (e.g., Syria, Iraq, Libya, Sudan, and Palestine) resulting in limitations of workforce and anesthesia access and safety in parts of these countries.

Pakistan (Fauzia Khan)

From the time Pakistan gained independence (1947) until the late 1950s, the practice of anesthesia was mostly limited to spinal or open-drop ether after induction with ethyl chloride. The first chair of anesthesia was established at the King Edward Medical College, Lahore, in 1959, and a 2-year diploma course (DA) was introduced at the same institution in 1960. The first ICU in Pakistan was established in 1976 at Mayo Hospital, Lahore, and the Pakistan Society of Anesthesia (PSA) was founded in 1971 in Karachi. A higher

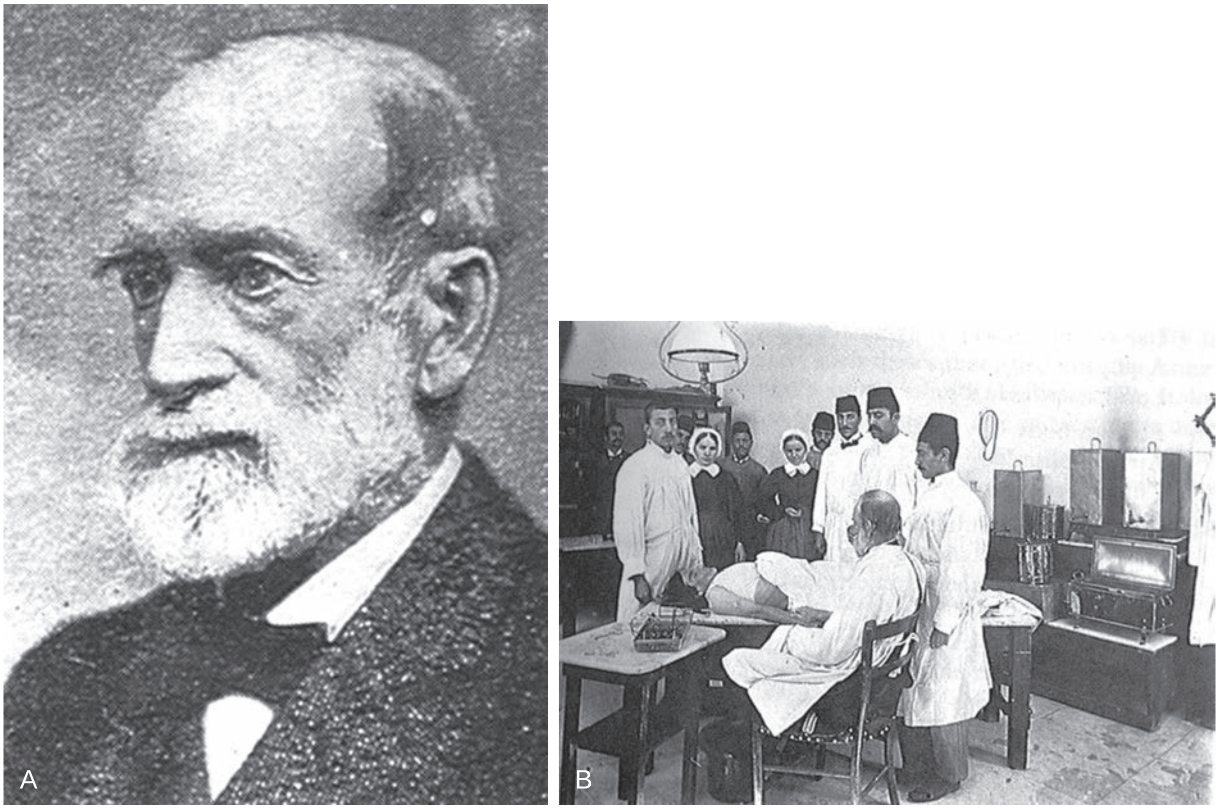

Fig. 2.17 Dr. George Post (A), in an operating room with a female patient on the table (B).

diploma, the Fellowship of the College of Physicians and Surgeons of Pakistan (FCPS), was instituted by the College of Physicians and Surgeons of Pakistan (CPSP) in 1972.

The CPSP includes anesthesia faculty and accredits all physician training programs in the country. Two training tracks are offered for anesthesia: (1) a higher professional diploma (FCPS) that requires 4 years of competency-based standardized training; and (2) a Membership of the College (MCPS) that requires 2 years of training after medical school and 1 year of internship. Only FCPS diploma holders can progress in the academic ladder in university anesthesia jobs. Certification in either track requires written, practical, and oral examinations. License to practice is provided by a separate body, the Pakistan Medical and Dental Council.

The anesthetic workforce in Pakistan is comprised of 3100 physician specialists (1.64 physician anesthetists per 100,000 population) (see Table 2.3). Anesthesia almost always is provided by physicians, although in some remote areas surgeons may administer local blocks or even spinal anesthesia. The main clinical responsibility for the majority of anesthesiologists is to provide operating room anesthesia and preoperative assessment, but in several institutions they also lead ICUs and chronic pain management clinics.

Health care in Pakistan is provided mainly by the private sector, with the government contributing only about 20% of services. Government-owned institutions are tiered into teaching, district, and county (taluka) hospitals. A system of basic health units provides primary health care. The majority of anesthesiologists hold two jobs as remuneration from just one is not sufficient. Only a few public institutions allow in-house private work by anesthesiologists. Brain drain is an ongoing issue with a significant proportion of the workforce emigrating to the Middle East or Europe.

There are currently no national guidelines relating to anesthesia and little awareness of international safety standards. There are also limited data on anesthesia outcomes in Pakistan.[202] There is no national body responsible for quality and safety in health care, however, the Punjab Healthcare Commission (PHC) is an autonomous health regulatory body created by the provincial government for the Punjab province (96 million people). The PHC aims to improve quality, safety, and efficiency of healthcare service delivery for the population of Punjab by implementing Minimum Service Delivery Standards (MSDS) in all areas and all disciplines including anesthesia. This model is soon to be replicated in the other provinces.

Anesthesia care varies significantly among health facilities within the country. Larger hospitals in bigger cities have access to modern equipment and monitors comparable to HICs. Many government teaching hospitals and secondary health centers are underfunded and have only basic equipment for monitoring (e.g., ECG and noninvasive blood pressure). Medication shortages are a frequent occurrence as several routine anesthetic medicines like fentanyl, inhalational agents, antiarrhythmics, and vasoactive drugs are imported. Even drugs manufactured within the country like morphine and ephedrine are frequently unavailable. Remifentanil, sufentanil, esmolol, S-ketamine, and clonidine are among many drugs not available at all due to licensing issues.

Additional challenges currently facing the Pakistani anesthesia community include maldistribution of human resources, limited biomedical technician support, and lack of political will. There is great necessity for regional collaboration to collect data on anesthesia and surgical need, resources, and outcomes to help improve safety and better allocate resources.[203]

China (Yugaung Huang)

Modern anesthesia was introduced along with Western medicine into China in the early 20th century. In the 1950s, only simple anesthesia care was available in China, including open-drop ether, tracheal intubation under inhalational anesthesia, and single-shot procaine spinal anesthesia together with peripheral nerve blocks. Because of economic limitations from the 1950s to the 1980s, intravenous procaine combined with opioid anesthesia and even acupuncture anesthesia were common. Anesthesiology in China has evolved in the past 2 decades as a crucial medical specialty that is integral to multidisciplinary surgical care and collaboration. This has resulted in modern anesthesiology shifting from narrowly focused on surgical anesthesia to perioperative medicine.

The training of anesthesia practitioners remains a big challenge. Currently in China, medical school studies range from 5 to 8 years resulting in an inevitable variation in educational quality. The national resident training program was initiated in 2000 and standardized in 2014, which will make the specialty catch up with the international standards of training and help to eliminate disparities due to difference in initial medical education.

To ensure patient safety, it is emphasized that clinical anesthesia is provided by anesthesiologists rather than anesthesia nurses. To meet the rapidly increasing needs outside of the operating room, anesthesiologists are required in nonsurgical diagnostic and therapeutic procedures for endoscopy, painless labor, and delivering optimal care to improve the quality of patient care throughout the hospital. With the economic boom, the majority of Chinese hospitals are equipped with sophisticated anesthetic machines and monitors and have a modern work environment. However, there are obvious variations in the quantity and quality of anesthesia devices and services among the different regions of China. In some small or medium-sized hospitals, there are no anesthetic gas monitors, defibrillators, or target-controlled infusion pumps.[204]

With the support from the National Health Commission (NHC), Chinese anesthesiology has been shifting from only operating room anesthesia to perioperative medicine and moving from a volume-based healthcare system to a value-based healthcare system. Anesthesia safety and quality assurance are of vital significance and great concern. The National Quality Assurance Center for Anesthesia was established with Professor Yuguang Huang as its leader in 2011. Thus far 31 Provincial Quality Assurance Centers have been established throughout mainland China. There have been only sporadic studies so far providing data on anesthesia safety and these have come from several large hospitals, while the current status in resource-limited medical settings remains to be explored.[205,206]

The anesthesia workforce shortage has become one of the greatest challenges in China as the number of surgeries has grown and the anesthesia demand increased without a concomitant increase in the number of anesthesiologists. The density of physician anesthesia providers is only 5.12 per 100,000 population in China, which is approximately 25% of that in the United States. To meet the urgent healthcare needs, Chinese anesthesiologists are struggling with heavy workloads, and thus have high burnout and low job satisfaction.[207] Long working hours, heavy workload, high acuity, and fast work pace are all factors associated with burnout and patient safety. Even with this effort only 10% of pregnant women can receive epidural analgesia during labor, and patients undergoing endoscopy have to be on long waiting lists for analgesia and sedation since anesthesia practitioners are mainly occupied with surgery in the operating rooms. To bridge the workforce gap, the Chinese government has made great efforts to emphasize the importance of anesthesiologists and anesthesiology nationwide with supportive documents focused on improving the perceptions and roles of the anesthesia specialty in medical care not only for patients but also for anesthesia professionals. It is encouraging to see that an increasing number of medical graduates are willing to join the profession of anesthesiology, which prognosticates well for the future.

With great efforts by the Chinese Society of Anesthesiology and Chinese Association of Anesthesiologists, Chinese anesthesiology has developed rapidly to provide patients with safer anesthesia and better quality of life. Challenges include variation in anesthesia safety, shortage of workforce, occupational burnout, and unbalanced working conditions across the country. Further efforts are anticipated to make anesthesia practice even better in China.

Vietnam (Thi Thanh Nguyen and Thang Cong Quyet)

The modern history of anesthesia in Vietnam dates as far back as 1975 only due to the loss of records during the war. During the war, anesthesia was usually administered by surgeons, and only occasionally by an anesthesiologist who had mainly been trained by French or American specialists. During the war, U.S. military anesthesiologists made multiple seminal discoveries that changed modern transfusion practices.[208,209] Following the war, Vietnamese doctors gradually took up anesthesia and in 1979, the Vietnam Society of Anesthesiologists was founded in Hanoi with 100 members and Professor Ton Duc Lang as its first president. The membership continued to expand and currently there are more than 1000 anesthesiologists in Vietnam. In 1980, with the help of Dr. J. Beiboer from The Netherlands, the Vietnam Society of Anesthesiologists joined the WFSA, the CASA, and various other specialist societies throughout the region.

During the past decade, the role of physician anesthesiologists in Southeast Asia has changed remarkably. Physician anesthesiologists have gained recognition by peers and the populace. Training in anesthesia was initially undertaken by surgeons concurrently with surgical training. In 1993 the first department of anesthesia was established at Hanoi Medical University. Other departments were soon established in Ho Chi Minh City, Hue, Can Tho, Thai Nguyen, and Hai Phong. Several different forms of training varying in duration from 1 to 5 years were introduced in order to fulfill different requirements throughout the country, and contemporary anesthesia training is based on both the American and French systems.

Medical school is 6 years in duration, though during times of war a 4-year option has existed for trainees who have already completed a 2-year nursing program. After medical school, graduates can enter a 3-year residency in anesthesia (24 months clinical and 12 months research), for which there are 30 spots per year in the country. Residents do not receive remuneration during training unless they are bonded to a hospital where they worked as a general practitioner between medical school and residency. Upon completing residency, graduates are awarded a Master's degree and can work as a "first specialist" anesthesiologist. Thereafter they can pursue additional training in either an academic pathway (2-year PhD) or a "practical" pathway with "second specialist" training (2 years of apprenticeship and consultant work). The "second specialist" certificate allows these providers to function as a consultant, head of anesthesiology or as a trainer in the practical training system. An additional anesthesia training pathway exists for medical school graduates who are not admitted to residency. These physicians must pass a 1-year anesthesia training program, pursue 2 years of clinical anesthesia practice, and then return to a medical university to complete 2 more years of anesthesia training. At the conclusion of this pathway, these providers receive a "first specialist" anesthesiologist certificate, functionally equivalent to anesthesiologists who have completed the practical pathway previously discussed. There are approximately 100 training spots available per year in the country for this anesthesia training pathway. There are no formal, accredited subspecialty training programs in Vietnam, although several institutions offer 6-month to 1-year certification programs for select subspecialties. Additional training opportunities for Vietnamese anesthesiologists have been introduced in France and Southeast Asia. Numerous Vietnamese anesthesiologists have participated in the Bangkok Anesthesia Regional Training Center (BARTC), a 1-year fellowship supported by the WFSA and the Royal College of Anesthesiologists of Thailand to train anesthesia educators in Asia.[210]

In addition to the courses for physician anesthesiologists, several courses for nurse anesthetists were also introduced, which varied in duration from 1 year for registered nurses to 3 years for new nursing students. Nurse anesthetists are required to always work with a physician anesthesia provider or with permission from the manager of the hospital. Physician and nurse anesthetists are now able to staff over 1000 hospitals and clinics throughout the country where surgery is undertaken. In 2012, the Ministry of Health issued guidelines for anesthesiologists to become involved in pain management and critical care in addition to preoperative, intraoperative, and postoperative care. These specialties require additional training and formal anesthesia subspecialty fellowships do not exist in Vietnam.

Prior to 1990 the major techniques used were inhalational anesthesia, first with ether and subsequently with halothane. Induction was with thiopentone or ketamine and regional anesthesia with spinal or epidural. Since 1990 the responsibilities of anesthetists have expanded to include specialist areas such as extracorporeal circulation for open heart surgery, organ transplantation, ultrasound-guided regional anesthesia, chronic pain management, preoperative assessment clinics, and out of operating room activities such as epidural analgesia for patients in labor, and anesthesia for endoscopic procedures. The WHO Surgical Safety Checklist is commonly applied in every operating room and clinical practice guidelines are selected from ASA or ESA guidelines. There is still a maldistribution of anesthesiologists, a shortage of essential medications, and lack of necessary infrastructure, which can endanger patient safety.

The Vietnam Society of Anesthesiologists is striving to raise standards of education in anesthesia to be at par with international standards in order to enhance the safety of the practice in the country, encourage scientific research among members, establish professional guidelines, and support working with the Ministry of Health to advance the specialty of anesthesia. At present there are no national examinations for certification.

SOUTH AMERICA

South America is a vast continent with a population of 420 million and economies ranging from the eighth largest in the world (Brazil) to some of the poorest in the world (Bolivia).[210a] Some cities or areas of cities have HIC health care including hospitals with top-level research and Joint Commission certification (77 in 6 countries) whereas many others do not even comply with national standards.[211] This is a reflection of the social difficulties of the continent where most countries have poor Gini indexes (measure of distribution of income of a country's residents) ranking among the worst in the world.[212]

Anesthesia workforce density in South America varies by more than 10-fold among countries (Uruguay 13.7 vs. Peru 1.7).[100] Substantial differences exist in practice models, ranging from physician-only anesthesia practice in Colombia to Paraguay where 50% of anesthesia is provided by nonphysicians. This translates into dramatic differences in resources where some hospitals have anesthesia information systems and sophisticated monitoring equipment (e.g., intraoperative transesophageal echocardiography with tissue Doppler, electroencephalograph monitoring), while most still rely on paper records and limited anesthesia machines. Training quality and capacity are also highly variable and few homogenizing mechanisms exist to guarantee a minimal standard of training, as certification mechanisms are virtually absent.

Paraguay (Rodrigo Sosa Argana)

The first reports of anesthesia in Paraguay are of chloroform use during the war Paraguay fought against the Triple Alliance (Brazil, Uruguay, and Argentina) between 1864 and 1870.[213] The country's first recorded physician anesthesia provider was Dr. Roberto Olmedo in 1928, and the first trained anesthesiologist Dr. Luis Ramirez is credited with starting the specialty in Paraguay in 1948. After this time, the number of anesthesiologists who trained abroad began to increase.[214]

The Sociedad Paraguaya de Anestesiología (SPA) was founded in 1973 by the 18 anesthesiologists practicing in the country at the time. The first anesthesia training programs were started in 1982, and the first formal anesthesia residency program (3 years in duration) was created in 1992 by the Hospital de Clinicas of the Universidad Nacional de Asunción.

In addition to physician anesthesiologists, the Ministry of Public Health and Social Welfare also licenses two types of nonphysician providers, technicians and diplomates. Technicians have no formal prerequisites and receive minimal if any formal training (most are taught as apprentices, historically most often by surgeons). Diplomates complete a 3-year anesthesia training program after high school that consists of once-weekly training days. These providers currently administer anesthesia in the most remote areas and public hospitals throughout the country, whereas physician anesthesiologists provide the majority of care in urban settings and the private sector. In the urban and private setting, the nonphysician cadres often work alongside physician anesthesiologists in a supportive role and with close supervision. The Ministry of Public Health has defined a scope of practice for nonphysicians in Paraguay such that they can perform anesthesia independently in remote locations where no anesthesiologists are present. In such circumstances, the nonphysicians are supervised by the surgeon and generally perform cases of lower complexity, most often under spinal anesthesia. There has been significant tension between all anesthesia cadres in the country. The technicians and diplomates consider their training and expertise as equivalent despite significant differences in prerequisites, training, and practice (see Table 2.3). In recent decades the number of physician anesthesiologists has increased relative to the number of nonphysician providers. There are approximately 258 anesthesiologists and 491 nonphysician providers (technicians and diplomates) in Paraguay (10.7 anesthesia providers per 100,000 people).

A major challenge in Paraguay at present is ensuring standards for anesthesia provider training. The SPA has lobbied the government extensively to curb nonphysician training in Paraguay due to ongoing concerns about the quality of training standards. In the last decade the SPA has been successful in enacting high-level education reform to improve anesthesia practice standards and has organized multiple international meetings including a recent large Latin American Anesthesia conference (CLASA 2013).

Colombia (Pedro Ibarra)

The first documented anesthetic in Colombia was provided in 1849 using chloroform.[215] In these early times, underperforming medical students were often relegated to providing anesthesia, and for many years anesthesia services were provided by poorly trained, and often nonmedical, personnel (e.g., technicians, healthcare students, and nurses). Dr. Isaac Rodriguez was the first Colombian physician dedicated to anesthesia, and the first formally trained anesthesiologist was Dr. Juan Jose Salamanca who trained under Dr. Henry Beecher at Massachusetts General Hospital in 1940. The Sociedad Colombiana de Anestesiologia y Reanimacion (SCARE) was founded in 1949 and was one of the founding societies of the WFSA in 1955. The first formal anesthesia training programs in Colombia were established in the 1960s, at Universidad Nacional and Universidad de Antioquia (UdeA). The Universidad Nacional program had input from Dr. Gustavo Delgado, who trained with several pioneers in anesthesia including Dr. Robert Dripps (see Fig. 2.16). The UdeA program was developed by Dr. Nacianceno Valencia, a second-generation "aqualumni" trained by Dr. Perry Volpitto (see Fig. 2.16).[216,217]

The first anesthesia residency programs (2 years in duration) began to increase the number of anesthesiologists in the 1960s, but the large magnitude of the workforce shortage forced several medical schools to introduce strong anesthesia training during medical school. This allowed medical school graduates to provide basic anesthesia care during their mandatory rural service year after graduation. They gradually reduced nonphysician anesthesia care in the 1970s in small towns. Many of these physicians remained in remote towns providing anesthesia care, until 1991 when the first law prohibiting anesthesia practice without a diploma was issued. Since the late 1990s, anesthesia care in Colombia has been exclusively provided by physician anesthesiologists.

Most of the 23 anesthesia residency programs are 3 years in duration (two programs are 4 years in duration) and are overseen by the Ministry of Education, which establishes curricular requirements based on input from the SCARE and the periodic Anesthesia Education Seminars that have been held since 1974. There is no national examination, and license for practice is issued by the Ministry of Health.

Currently there are approximately 3600 anesthesiologists in Colombia for a density of 7.9 anesthesiologists per 100,000 people. Approximately 115 anesthesiology trainees graduate each year, and a nearly matching number of foreigners or foreign-trained Colombians are incorporated into the workforce. In recent years, political and economic uncertainties in Venezuela have increased the influx of foreign-trained anesthesiologists into Colombia. In some cases, this increased supply has driven down remuneration and created tension with locally-trained anesthesiologists.

Rural anesthesia staffing is a significant challenge in Colombia. The needs of remote areas are often met through economic incentives and temporary positions. Rural hospitals pay premium salaries for positions that are difficult to fill and are able to do so because nearly 100% of Colombian citizens have healthcare coverage through the government-funded, multi-institutional insurance scheme. This single-payer approach allows rural hospitals to receive reimbursement comparable to institutions with higher-income, urban patient mixes. Because competition for anesthesia jobs is less in rural than urban settings, some rural hospitals are able to put together competitive compensation packages and recruit more easily than some public institutions in urban settings where reimbursement is lower and competition for jobs is higher.

The first Colombian anesthesia standards were published in 1985, and in 1992 a modern version based on the ASA Standards was published by SCARE and adopted by the Colombian government. The WHO Surgical Safety Checklist was adopted in 2008 and has contributed to the decreasing incidence of malpractice cases involving anesthesiology. Malpractice suits are a significant challenge in Colombia as well as a driver for improved safety. In 1993, SCARE created an anesthesia malpractice defense fund, FEPASDE, which became the major malpractice insurer for the country. To maintain the economic health of the fund, SCARE has adopted national healthcare education strategies for adverse outcome prevention.

Colombia's healthcare system faces several additional challenges. One is economic sustainability, due to healthcare benefits in excess of national resources. A second is regional inequity, where healthcare quality differs dramatically between regions. An additional major challenge is the ongoing workforce shortage. One driver of the health worker shortage is the present training system, which requires residents to pay tuition during specialist training. There is an effort in the Congress of Colombia to eliminate this practice. As with many other LMICs, remuneration is a major challenge for anesthesia providers in Colombia who frequently work more than one full-time position to increase salary. This has expanded anesthesia coverage but also increased the risk of provider burnout.

OCEANIA

There are 16 independent nations in the region of Oceania. This area of the South Western Pacific accounts for approximately 30% of the world's surface area but has less than 40 million people with over 70% of people living in Australia and New Zealand. Of the independent island nations, Papua New Guinea is the most populous with over 8 million people and Tuvalu the least populous with approximately 11,000 people. The region consists of many remote islands and is economically diverse with only Australia and New Zealand being considered as HICs. Australia and New Zealand will be considered together and the independent island nations of Fiji, Solomon Islands, Vanuatu, Tonga, Papua New Guinea, Marshall Islands, Micronesia, Nauru, Samoa, Tuvalu, Palau, and Kiribati will be considered as one group.

Australia and New Zealand (Rob McDougall)

News of the first use of ether for anesthesia reached Australia by sailing ship in May 1847 and soon after, ether was used for a dental procedure in Sydney and general surgery in Launceston.[218] Later that year saw the first use of anesthesia in New Zealand, again following news by ship.[219] In 1888 "chloroformists" were first appointed in Australian hospitals but it was not until 1944 that the first university diploma course in anesthesia was established.[220] The Australian Society of Anaesthetists was established in 1934 and the New Zealand Society of Anaesthetists (NZSA) followed in 1948.

Anesthesia in Australia and New Zealand is provided by physicians. Training, examination, and accreditation of Australian and New Zealand anesthesiologists is the responsibility of the Australian and New Zealand College of Anaesthetists (ANZCA), which was founded in 1992. Prior to this time, specialist training was administered by the Faculty of Anaesthetists of the Royal Australasian College of Surgeons, which was formed in 1952. ANZCA established the Faculty of Pain Medicine in 1998 and pain medicine was recognized as a medical specialty in Australia in 2005. In addition, ANZCA is responsible for the standards of clinical practice of anesthesia and pain medicine in Australia and New Zealand.

Australia and New Zealand have among the highest density of anesthesia providers, in population terms, in the world with 23.09 and 21.79 anesthesia providers per 100,000 population, respectively.[100] A minimum of 7 years of postgraduate training is required to become a specialist anesthesiologist.

Specialist anesthetists account for almost the entire anesthesia workforce in New Zealand, however, Australia has an active body of over 250 GP anesthetists, who predominantly work in regional and remote areas which cannot sustain full-time specialist anesthetists.[221] The training and accreditation of GP anesthetists is overseen by ANZCA and the Royal Australian College of General Practitioners. The provision of high-quality anesthesia in remote areas of Australia continues to be a challenge.

In 2014, the average age of the Australian anesthesiologist workforce was 49 years and 27% of the workforce was female. Australia and New Zealand have publicly funded universal health care but both countries have a private health sector. Just over 50% of work by Australian anesthesiologists was in the public sector.

ANZCA has produced triennial reports on anesthesia-related mortality in Australia and New Zealand since the first comprehensive report for 1985–87. For 2012–14 the anesthesia-related mortality for Australia was 2.96 deaths per million population per annum or 1 death for 57,023 episodes of anesthesia care.[222] In addition, New Zealand is one of the few countries to comprehensively collect and report 30-day POMR. POMR is one of the core indicators recommended by the LCOGS for monitoring safe surgery and anesthesia. Thirty-day POMR in New Zealand for 2010–15 was 0.55% of hospital admissions receiving general anesthesia.[223]

In spite of its huge size, Australia is one of the world's most urbanized countries. This aids centralization of health care but does create equity of access challenges for those living in remote areas. This is a particular problem for indigenous Australians who account for almost half the population of very remote areas.

Australian and New Zealand anesthesiologists are involved in global health activities, particularly in the Asia Pacific region. Both the Australian Society of Anaesthetists and NZSA are active members of the WFSA and also have their own global outreach committees. ANZCA also has a strong Overseas Aid Committee. The Overseas Development and Education Committee of the Australian Society of Anaesthetists has long supported the development of anesthesia in the Pacific, in partnership with the Pacific Society of Anesthetists and the Fiji National University (FNU). ANZCA has similarly supported Papua New Guinea in partnership with the Society of Anesthetists of Papua New Guinea and the University of Papua New Guinea (UPNG). Similar partnerships exist between professional organizations in such countries as Mongolia, Myanmar, Timor-Leste, Micronesia, Solomon Islands, Laos, Cambodia, and other Pacific Island nations. Essential Pain Management, Primary Trauma Care, and Lifebox are examples of programs coordinated by Australian and New Zealand professional bodies in the Asia Pacific region.

Fiji and Pacific Island Nations (Sereima Bale)

The remote geographic locations of the myriad of small and large islands that comprise the Pacific Island nations and their diverse populations make the training and the practice of anesthesia a massive challenge.

In Fiji, Papua New Guinea, and Pacific Island countries, Assistant Medical Practitioners or Anaesthetic Technical Officers were trained as apprentices by expatriate consultant anesthetists during the various colonial eras before each country gained independence. Anesthesia became a recognized specialist discipline in 1970 in Fiji even though doctors (registered as "Native Medical Practitioner") had been practicing as "anesthetists" since the 1920s.

In the early 1970s, many Pacific Island nations (Fiji, Tonga, Kiribati, Niue) sent their doctors for training in the DA program offered by the Anesthesiology Center for the Western Pacific (Manila, Philippines) in collaboration with the WHO Western Pacific Regional Office. Currently the two specialist training institutions in this region are the College of Medicine, Nursing and Health Sciences of the Fiji National University (FNU), which started anesthesia training in 1996, and the University of Papua New Guinea (UPNG), which established anesthesia training in 1989 as the Fiji School of Medicine. These programs offer physicians a 1-year DA, that may be followed by a 3-year anesthesia Master's of Medicine (MMed) as the specialist qualification. Since 1996, FNU has graduated 92 doctors with the DA, and 39 of these have gone on to receive the MMed. There have been 32 anesthesia specialists that have graduated—23 from Fiji and 16 from other Pacific nations.

FNU trains only physicians while UPNG also offers a 1-year diploma course for healthcare workers who train as Anaesthesia Scientific Officers (ASOs). These NPAPs provide 90% of anesthesia services in Papua New Guinea, often in remote provincial and mission hospitals with no physician supervision. Other Pacific Islands that utilize this latter cadre of NPAPs to complement their physician capacity are Vanuatu, Tonga, and Solomon Islands. Other islands in the northern Pacific, including former U.S. territories, employ American-trained nurse anesthetists.[224]

Two issues significantly limit the development of the anesthesia workforce in the Pacific: (1) few students graduate from medical schools in Fiji and Papua New Guinea to supply any specialties and keep pace with growing populations; and (2) few job opportunities are funded by national Ministries of Health. In Fiji for example, there are 23 physician specialist anesthesiologists for a population of 800,000, but only 5 consultant positions supported by the Ministry of Health, which employs all Fijian FNU graduates. Additional challenges routinely faced in the region include limited access to equipment, geographic isolation, and an influx of medical graduates from other regions who may be ill-prepared for postgraduate training or practice in this setting.

In 2018, Fiji (population 800,000) had 18 specialists. Unless there is significant expansion of job opportunities for specialist anesthesiologists, limited access to specialist-level care is likely to continue regardless of numbers of graduates. There is continuing brain drain among graduate specialists in Fiji. Of the 23 MMed graduates, only 17 remain in government employment with minimal opportunities for private practice. Some of these graduates, however, remain in practice in the Pacific, just not in their country of origin.

Other Pacific Islands are continuing to build their capacity and are retaining their graduates: Kiribati (2 MMeds, 1 DA: population 33,000); Solomon Islands (4 MMeds; population 600,000). The volume and range of cases in the smaller island nations pose different challenges. The solo anesthetist who may provide anesthesia for 1 to 2 surgical lists per week may also be required to cover other clinical or administrative services as necessary. In addition, this officer is also expected to cover for emergencies and is permanently on call. Outdated skills and knowledge can develop as can burnout as a result of professional isolation and lack of support.

Papua New Guinea is a LMIC on the eastern half of the island of New Guinea (the second largest island in the world) and has only 19 physician specialist anesthesiologists and 130 ASOs, of which only 50% are currently employed. The challenges of the provision of safe surgery and anesthesia in Papua New Guinea relate to its terrain and poverty. Eighty percent of the population live in remote highland, coastal, and island villages and may be days away from a hospital that can provide the three bellwether procedures. Currently Papua New Guinea has 0.25 PAPs per 100,000 compared with Australia and New Zealand where the anesthesia workforce is 75 times greater.[224]

There are three main anesthesia societies in the western Pacific outside of Australia and New Zealand: The Pacific Society of Anaesthetists (28 members); the Micronesia Society of Anesthetists (7 members); and the Society of Anaesthetists of Papua New Guinea (16 members). All Pacific societies have received varying support from the Australian and New Zealand governments, the ASA, the NZSA, ANZCA, and the WFSA, and hosted joint meetings for the first time in 2014.

Section 3: Essentials for Practice in Resource-Constrained Settings

CLINICAL AND TECHNICAL SKILLS

The practice of anesthesia anywhere in the world is reliant on four principle factors: personnel, equipment, medications, and patients with their comorbidities. Disruption, change, or lack of any of these factors may limit the safe practice of anesthesia. Whether practicing in a rural HIC setting, an LMIC, a military or humanitarian field hospital, or other resource-constrained setting, all of these will be modified. Data guiding practice in these settings are limited and may be interpreted differently. There are numerous instances of well-intentioned, evidence-based practices from HICs producing unintended negative consequences in LMICs.[225]

Clinical practice in resource-constrained settings may be extremely different from what one may be accustomed to, so it is important to understand the local context before attempting to change anything. There is often a logical reason why practice patterns diverge from the "standard," and frequently this has less to do with local providers "not knowing the right way" and more to do with local challenges related to personnel, equipment, medications, or patients. This section will briefly discuss select aspects of anesthesia practice in resource-constrained settings through the lens of these four factors.

Personnel. Limitations in anesthesia workforce are one of the most significant barriers to the safe provision of anesthesia care worldwide. Beyond low absolute numbers of providers, the competencies of existing anesthetic providers may be highly variable. Many practitioners who provide anesthesia in resource-constrained settings may have completed inadequate training and often work in isolation with negligible supervision or colleague support. Many are highly skilled and competent within a narrow spectrum of clinical cases, and often learn to deliver a "recipe" type anesthetic that may not be adaptable or appropriate for more complex cases.

When working in resource-constrained environments, it is important to understand the level of knowledge and experience of the local anesthetic provider. Regardless of training level, there are always opportunities for mutually beneficial bidirectional learning. The role of the anesthetic provider in many resource-constrained settings is often limited to the operating theater, as the concept of perioperative care is underdeveloped and not part of training. Personnel shortages routinely limit capacity for adequate preoperative evaluation (including resuscitation) or routine postoperative monitoring. Staffing (e.g., perioperative nursing) may be entirely lacking, and routine elements of postoperative care such as monitoring or providing regular pain assessments with analgesic administration are rarely available. Thoughtful planning is required especially if higher-level care is needed postoperatively (e.g., ventilation), as this usually will become the responsibility of the anesthesia provider or even family members (who are frequently recruited to help with monitoring or even manual ventilation). The PACU may consist of an unstaffed corridor or a small designated space near the operating room complex exit. In this setting, it is paramount to ensure patients are more fully recovered from their anesthetic when they arrive in the recovery area than may be routine in well-resourced PACUs.

Equipment. Anesthesia Machines: Most modern anesthetic workstations cannot function without pressurized gases and electricity, both of which may be in short supply in many resource-constrained environments. In these settings, familiarity with drawover anesthesia may be essential. In-depth discussion of drawover anesthesia is beyond the scope of this chapter, however, knowledge of drawover anesthesia is highly relevant in many practice settings, and several comprehensive resources for learning drawover are included at the end of this chapter. Here we provide a brief overview of the basics of drawover anesthesia.

An inhalational anesthesia system must be able to deliver accurate concentrations of volatile agent, avoid rebreathing of carbon dioxide, have a provision for intermittent positive-pressure ventilation (IPPV), and provide oxygen-enriched gases. Unlike more complex anesthesia machines, drawover systems do not require compressed gas or power, can function on room air, and cannot deliver hypoxic gas mixtures (which is especially relevant where inspired oxygen monitors may be lacking). A drawover system consists of a temperature-compensated or buffered, low-resistance vaporizer (calibrated to the agent), a self-inflating bag or bellows with a one-way valve upstream to ensure unidirectional gas flow to the patient, and a non-rebreather valve at the patient end to avoid rebreathing of carbon dioxide (Fig. 2.18). Drawover setups that can function with multiple volatile agents are most versatile (i.e., in the event that one volatile agent is unavailable), and providers should be familiar with technical aspects of using the same vaporizer for different volatile agents. The self-inflating bellows (SIB) can be used for IPPV (by hand) and may show movement or a small palpable pressure change with respiration that enables the anesthesia provider to monitor respiratory rate in the spontaneous mode. Air is the “driving” gas (although “sucking” gas might be a more accurate description) in a drawover system, but oxygen supplementation is possible with addition of oxygen at the vaporizer inlet or with the addition of a piece of reservoir tubing or bag. The ability to function on ambient air is a critical safety feature of all drawover setups. Without some form of reservoir, it is impossible to achieve a fraction of inspired oxygen concentration (FiO2) above 0.3 regardless of oxygen flow. With just one meter of standard adult reservoir tubing (22 mm diameter), 4 L per minute can give an FiO_2 of over 0.6 and a flow of 1 L per minute gives an FiO_2 of 0.3. The gas flow, which is dependent on the patient’s tidal volume and respiratory rate, is highly variable, but most vaporizers (OMV, DDV, EMO) (see Fig. 2.18) remain extremely accurate as long as the gas flow is intermittent. However, they often lose their accuracy when the system is converted to a continuous flow mode.

Although the drawover system is low resistance, in some situations it may be advisable to convert it to a continuous flow system when anesthetizing babies to overcome the dead space at the level of the non-rebreather valve. This can be done manually by creating a flow using either an Oxford inflating bellows or self-inflating bag. The bellows are jerked up to their full capacity and then released slowly. This is done 6 times per minute to create a continuous flow through the vaporizer. This flow of oxygen-enriched air supplies an Ayre’s T-piece attached to the outlet of the bellows. Both valves need to be in use to ensure unidirectional flow as this is still a low-pressure system (Fig. 2.19). If using a self-inflating bag then it must be squeezed and released 12 times per minute. This manual system mimics adult drawover with a more intermittent flow, and the vaporizers tend to still provide an accurate reading as opposed to full continuous flow using either a Farman’s entrainer or direct attachment of an oxygen source to the inlet of a vaporizer. Whatever equipment you have at your disposal it is probably simpler to follow these approximate guidelines:

If <5 kg, assisted ventilation for whatever the length of the operation.
If 5-10 kg, spontaneous ventilation for short cases and assisted ventilation for longer procedures.
If >10 kg, spontaneous ventilation for most operations, unless paralysis is required or the procedure is prolonged.

There are a small number of all-in-one drawover anesthetic machines based on the same principles as the portable drawover systems (Fig. 2.20). They are not plenum machines, and supplemental oxygen can be supplied from a cylinder or an integrated oxygen concentrator. These machines are significantly less expensive and relatively easier to maintain than many other anesthesia machines. They can also function without power and without supplemental or pressurized oxygen, making them ideal for some resource-constrained settings. Integrated, uninterruptable power supplies (UPS) provide power for certain functions (e.g., monitors) in the event of power failure, and some versions include integrated ventilators. The companies that manufacture the Universal Anesthesia Machine (Gradian Health) and the Glostavent (Diamedica [UK] Ltd) both invest considerable resources to ensure local expertise for operation, training, and service support. These elements are critical for successful utilization of equipment in resource-constrained settings. Regardless of the anesthesia setup employed, a plan for power or oxygen failure is essential and likely to differ based on the setting.

Oxygen Concentrators: In many countries pressurized oxygen is available primarily via cylinders, but the supply may be unreliable or cost prohibitive, and therefore a backup is essential. Providers working in resource-constrained settings should have familiarity with at least the basics of function and maintenance for various oxygen delivery solutions including concentrators. Oxygen concentrators use a technique called pressure swing adsorption and zeolite crystals to extract nitrogen from air to produce oxygen with 90% to 96% purity, although purity drops to around 85% with higher flow rates. In principle, most oxygen concentrators are relatively similar, and non-engineers can often diagnose and fix common problems (e.g., dirty filters, low voltage, compressor or valve system failure, excess flow, or hot ambient temperatures)[226] (see the Appendix 1 for links and useful resources including the WHO guide to oxygen concentrator maintenance). In reality, not all oxygen concentrators are designed to function in all climates, and many do not conform to WHO guidelines.[226,227] In a performance study of eight oxygen concentrators, only two models delivered greater than 82% inspired oxygen concentration at 35°C and 50% relative humidity.[228] Oxygen concentrators can be used to provide supplemental oxygen in the operating theater (via drawover system), the PACU, or the ward. Makeshift splitting of a single oxygen source to supply multiple patients on the ward is a common practice although it can easily result in inadequate inspired oxygen fractions. A small, portable oxygen analyzer can be useful to test the output of concentrators and cylinders as some facilities lack the infrastructure to ensure necessary quality control. Submerging the terminal end of parallel oxygen delivery circuits into cups of water can allow for comparison of gas flow rates.

Monitors: Many operating theaters around the world have minimal monitoring options despite the international standards set out by the WHO and WFSA.[3] In this environment there is increased reliance on clinical skills (e.g., change in palpable pulse volume, degree of chest expansion, pupil size, and change in compliance of bellows, self-inflating bag, or bag on Ayre's T-piece). Because electricity may be unreliable, ideally monitors should have a functional internal battery. Pulse oximetry is invaluable but not universally available. Some inexpensive pulse oximeters meet international quality standards, however, few are designed for harsh environments, and many are extremely inaccurate.[229] The Lifebox initiative is one of the first initiatives to help design and distribute pulse oximeters that meet the demands of LMICs (i.e., affordable, accurate, durable, with audible alarms and specially designed, reusable probes that work with neonates and adults).[230] Precordial stethoscopes are particularly useful and can be made from an ordinary stethoscope with an extension (e.g., suction tube or oxygen tubing). Precordial stethoscopes provide an excellent beat-to-beat heart rate monitor and continuous, audible verification of respiratory rate, airway patency, and endotracheal tube placement. Hypovolemia may be detectable by a decrease in heartbeat tone that is apparent prior to alarms on other monitors.

Airway Equipment: In resource-limited settings it is often absolutely essential to maintain spontaneous respiration and oxygenation with a difficult airway until the airway has been secured. Face mask ventilation with a Guedel or nasopharyngeal airway, regional anesthesia, or ketamine-based anesthetics may be safer than attempting complex airway management. An awake look with direct laryngoscopy can often assist in airway management planning. Safety is key and it may be preferable to opt for a tracheostomy under local anesthesia as the surgical skills may be superior to what is feasible with the limited anesthetic equipment and ability. As advanced airway equipment and experienced assistance is likely to be lacking, excellent technique and positioning for laryngoscopy is crucial for success. Many hospitals providing surgical care will have only a Macintosh size 3 laryngoscope blade, and rarely additional equipment such as a bougie. Retrograde intubation and blind nasal intubation can be useful skills to master. Airway topicalization can be accomplished many ways, including transtracheal lidocaine injection or by gargling or spraying water-based lubricant jelly, lidocaine, and epinephrine. For blind nasal intubation, the tube is pushed forward during inspiration following the base of the nose, listening to the noise of breathing (similar technique to a Patil guide). If the tube enters the esophagus the neck should be extended, and if it impinges on the anterior part of the larynx, the neck should be flexed. Lifting the jaw will stop the endotracheal tube from hitting the epiglottis. Rotating the tube or inflating the cuff slightly may also assist with entering the trachea. If capnography is not available then condensation in the tube, movement of the bag with respiration, auscultation of the chest, and in rare circumstances an esophageal bulb can help verify correct placement. In LMICs, laryngeal mask airways may not be available and face masks, Guedel or nasopharyngeal airways, and endotracheal tubes are often washed and reused. There are a number of products that can be used to easily decontaminate endotracheal tubes, laryngeal mask airways, and other airway equipment, however, access is highly variable. When processing and reusing such equipment, damage to the cuff and increasing stiffness of the plastic are significant challenges.

Endotracheal tube stylets are infrequently available. Improvised endotracheal tube introducers have been crafted by carefully inserting a piece of wire into an appropriately sized suction catheter, taking care that the metal tip is not protruding. Learning safe, sensible techniques that are reproducible without the use of expensive, specialized equipment is fundamental. Where traditional electric suction is unavailable, bulb suction (for neonates) and foot pedal suction devices are invaluable.

Equipment for regional anesthesia: Spinal anesthesia is universally taught and used in many settings though may be used for a wider variety of cases than is commonly done in HICs (e.g., appendectomy). The needles vary in quality and blunt tips can be overcome by using a 21-gauge hypodermic needle as an introducer. The most commonly used local anesthetic is hyperbaric 0.5% bupivacaine. All anesthetic providers are taught to do spinals, but not all are taught how to prevent supine hypotension during spinal anesthesia. Teaching how to fabricate a simple wedge for uterine tilt with pregnant patients, or learning to reposition patients in varying degrees of reverse Trendelendberg position may prevent untoward incidents especially where an adjustable operating table may not exist. Although a spinal might seem like an easier and safer option, appropriate patient selection is critical, especially where preferred vasopressors and fluids may be in short supply. In that situation 0.5 mg epinephrine has been diluted in a 500 mL bottle of 5% dextrose and administered cautiously to treat the hypotension. Epidurals are rarely available in low-resource settings for several reasons: providers may not be proficient with the technique; needles are not commonly found; preservative-free local anesthetic drugs are not readily available for postoperative infusions; and more importantly, the staffing ratio may be inadequate and the knowledge may be insufficient to manage an infusion in the postoperative setting. In some settings where electronic drug infusion pumps are unavailable, low-cost elastomeric bulb pumps can be used to deliver a fixed rate of medication. Caudal blocks using a 22-G cannula are commonly used in children for postoperative pain management although the only safe preparation of local anesthetic may be the spinal bupivacaine.

Ultrasound or nerve stimulators are rarely available but many blocks can be performed using landmark or blind techniques (e.g., ankle, digital, axillary, penile, wrist, fascia iliaca, femoral, and rectus sheath blocks). Local field blocks may be used for a wide variety of procedures, including hernias, which are often done under local anesthesia in the outpatient setting. Where ultrasounds are available, other regional supplies may be lacking such as ultrasound gel, probe covers, echogenic needles, and appropriate local anesthetics. Several workarounds to these common challenges have been well-described. Although many blocks can be done relatively easily and safely without ultrasound or nerve stimulation, serious complications can still occur. Anecdotal reports of local anesthetic toxicity fatalities during penile blocks for circumcision are still encountered in some LICs and attributed to preventable causes (incorrect dosing or technique).[231] In general, distal blocks with lower volume and shorter-acting local anesthetics may be safer options, especially where safety equipment may be limited (e.g., intralipid).

Equipment for venous access: Intravenous cannulas are almost universally obtainable but variable quality may limit use. Needles may be blunt or extend quite a few millimeters beyond the tip of the cannula. Scalp veins are a common site for insertion in critically-ill infants, and with appropriate training, rapid placement of a cannula in the right internal jugular vein or in the peritoneal cavity can be lifesaving in a child dying from hypovolemic shock (e.g., cholera) as you look for a more permanent solution. Intraosseous needles are not easily found, but 18-G or 16-G needles can be used in the tibia of an infant. Butterfly needles, if available, are particularly useful because of the limited length. Twisting is essential to pierce the cortex until a sudden give when entering the medullary cavity. It is feasible to perform anesthesia for an entire operation with such access (Fig. 2.21).

Infusions pumps are often not available in LMICs and when present, are frequently limited by the availability of compatible disposables (i.e., appropriately sized syringes or proprietary tubing). It is important to not only be proficient with calculating infusion rates based on drop factor (drops per mL) but also be aware that infusion sets vary in size and quality, often making accurate calibration challenging.

Drugs. Volatile agents: Ether has now been removed from the WHO Essential Medicines List, and its use has reduced dramatically since 2013. Both isoflurane and halothane are included in the WHO Essential Medicines List, and due to the price differential (e.g., in Uganda 250 mL of halothane ~$21; 250 mL of isoflurane ~$39; 250 mL of sevoflurane ~$250), halothane is the most commonly used agent in many rural or non-teaching hospitals in LICs. Halothane is potent (MAC 0.8%) and sweet smelling, but the blood gas partition coefficient is 2.4 making the onset and offset of anesthesia slower than some agents. This can be useful if managing a difficult airway and intubation under halothane alone. Halothane is a cardio-depressant and arrhythmogenic especially in the presence of an elevated end-tidal carbon dioxide. It is useful for inhalational induction, but it is important to rapidly reduce the inspired concentration once intravenous access is

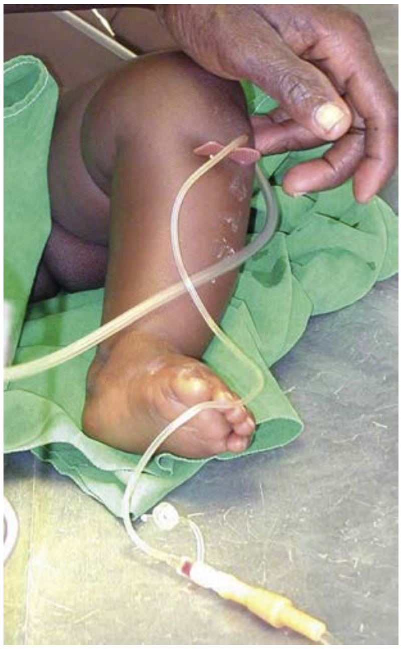

Fig. 2.21 Improvised intraosseous access catheter in a pediatric patient in Uganda. (Copyright © 2018 Sarah Hodges.)

secured. Nitrous oxide may be obtainable in some locations (primarily urban areas) but can be extremely expensive. Because medical-grade air (FiO_2 0.21) is often 4 to 5 times more expensive than oxygen, it is often unavailable and cases may be done on 100% inspired oxygen concentration.

Induction agents: The use of propofol is widespread but ketamine (in addition to volatile agents) remains the most ubiquitous induction agent in many LMICs. Thiopentone (thiopental) is also frequently encountered outside of HICs. Ketamine resembles an intravenous preparation of ether (sympathomimetic, does not depress airway reflexes, causes excessive salivation, and has excellent analgesic properties). S-ketamine is a useful adjunct for regional anesthesia. Ketamine can be used as an infusion (intravenous or subcutaneous injection) postoperatively for the management of pain especially if opioids are in short supply.[232] Ketamine can also be used for total intravenous anesthesia for a variety of procedures (e.g., laparotomies), but the wakeup can be very prolonged, and the patient may experience disturbing hallucinations as benzodiazepines are often not used (provider more likely to encounter diazepam than midazolam in resource-constrained settings). Ketamine is the “go-to” induction agent for any patient in hypovolemic or septic shock, but it can cause cardiac arrest in patients who are maximally sympathetically stimulated. Ketamine may be advised against as the sole anesthetic for pregnant patients undergoing non-obstetric procedures due to its potential oxytocic effects. Ketamine can also cause apnea in neonates, despite the appearance of the neonate moving in response to surgery. Special attention and caution must be emphasized in these patient populations. Because of ketamine’s overall safety profile, the drug has been used as the basis for a 5-day course to teach mid-level non-anesthesia providers to administer emergency anesthesia in rural sub-Saharan Africa when no anesthesia provider is available. This program has generated significant controversy and highlights many of the challenges facing the provision of anesthesia in LMICs.[233,234]

Analgesics: Morphine is often the most readily available opioid, although for many LMICs it is frequently challenging to obtain. In some countries where palliative care is more developed (e.g., Uganda), the oral formulation is often available for postoperative analgesia. Pethidine (meperidine) is commonly encountered in LMICs and used routinely for perioperative analgesia. Of note, pethidine is not included in the WHO Essential Medicines List, and it is not recommended for routine acute postoperative pain because of its variable efficacy and side effects. Nonetheless, pethidine may be the only option for analgesia in some LMICs and general familiarity with its pharmacology could be highly useful in select settings (see Chapter 24). As discussed earlier in this chapter, opiophobia and access limitations significantly restrict the use of opiates. As a result, if available, opiates are rarely prescribed beyond 48 hours postoperatively in many resource-constrained settings. Many analgesics (e.g., ketamine, morphine, and pethidine) are frequently given by intramuscular injection, which may have benefits in terms of feasibility and safety, although supporting data are limited.[232] Patient-controlled analgesia is generally unavailable, but in some settings has been substituted by using a small subcutaneous cannula, often placed over the deltoid muscle, used solely for parenteral opiate analgesics. This avoids repeated intramuscular injections especially in children and can remain in place for 48 to 72 hours. Tramadol is pervasive, inexpensive, and often used for perioperative pain management in resource-limited settings. Use of tramadol requires an understanding of its limitations including side effects, abuse potential, and inferiority in many instances to opioid analgesia.

Paracetamol (acetaminophen) is widely available as tablets, suppositories, syrups, and as an intravenous preparation as are nonsteroidal antiinflammatory drugs. Parenteral preparations vary from country to country as does the potency depending on the country of manufacture. Diclofenac is commonly found and intramuscularly injected. One of the major challenges with prescribing analgesics is conveying the concept of multimodal analgesia. Although the full spectrum of analgesic modalities may not be available, multiple analgesic options, including regional anesthesia, are often feasible in low-resource settings.

Muscle relaxants: Suxamethonium (succinylcholine) is a universally available muscle relaxant and may be the safest paralytic to use if there are no means for mechanical ventilation or availability for reversal. It rarely causes malignant hyperpyrexia although it can induce masseter spasm especially in children with neurologic or muscular disorders. Both atracurium and suxamethonium lose potency with exposure to heat and maintaining cold storage is a significant challenge in many settings. For cases where surgeons prefer paralysis for closure (e.g., laparotomy), a small dose of suxamethonium can be administered at the end of the case to facilitate closure of the peritoneum and rectus, while hand ventilating the patient and allowing faster offset of the volatile agent. The availability of nondepolarizing neuromuscular blocking agents is highly variable, and providers should be prepared to use drugs they may not readily use in HICs.

Lack of access to transfusion services (as discussed in the section, Anesthesia and Global Health) is another commonly encountered problem that may require improvisation. Providers in resource-constrained settings may be tasked with ABO typing (e.g., EldonCard) and cross-matching and should be familiar with these techniques. Whole blood transfusion may be more common than component therapy, although there are several notable limitations (including potential loss of platelet and clotting factor activity with refrigeration). Absolute transfusion thresholds are lacking but can create significant dilemmas. For example, is it safe to perform a hernia with a hemoglobin of 9, 8, 7, or lower if no blood products are available? Direct donation from patients or relatives as well as mandatory exchange (i.e., someone must donate in order for units to be released from the blood bank) are variably practiced in LMICs. Other practices such as preoperative normovolemic hemodilution and makeshift intraoperative blood salvaging (e.g., by using a cup, gauze filter, anticoagulant, and a 60 mL syringe) have been reported, but as of yet there is no safe, effective substitute for transfusion services in many settings.[235,236]

Patients. Anesthesia providers in resource-constrained settings must be comfortable with a wide range of potential surgical patients, especially trauma, obstetric (e.g., postpartum hemorrhage), and pediatric patients. In many LMICs, more than 50% of the population is under the age of 18, and most have fewer comorbidities and less polypharmacy than in HICs. On the other hand, patients often present late with advanced pathology. This may be due to a wide range of factors affecting access to care, including physical access to the health unit (unpassable roads in the rainy season, or insecurity on the roads), or they have been consulting the local healer or bone setter and have not seen any improvement, or they are financially destitute and all health care is financially and socially draining.

As relatives often provide most of the in-hospital care (e.g., cook the food, wash the bedding and clothes), an inpatient stay is extremely time consuming and no family will want their patient to be in hospital longer than necessary. Patients will mobilize more rapidly but may also be less compliant with postoperative instructions. Although patients may have lower incidence of chronic cardiac and respiratory comorbidities, many may be anemic, malnourished, or harboring low-grade malaria or helminth infections. If major surgery is being considered, existing maladies may need to be treated first and can prolong the inpatient stay. Multiple preoperative investigations may not be affordable or feasible and many decisions are made solely on clinical judgment.

Anesthesia providers practicing in LMICs must be familiar with perioperative optimization of commonly encountered conditions. Treatment for universally common conditions such as hypertension or diabetes may require context-specific approaches and insights (e.g., where and how to provide temperature-stable, noncounterfeit medications).

The practice of anesthesia in the resource-limited setting is shackled by many issues, and it can be challenging to attempt to administer a high level of care as advocated by many professional entities. Anesthesia safety is an essential component of care. Are there standards of care that are immutable across the globe? If a full term pregnant woman is admitted to hospital with a severe antepartum hemorrhage that requires an emergency cesarean section to save the mother and baby, what is the anesthetic of choice? Is it local anesthetic infiltration alone, intermittent aliquots of intravenous ketamine and oxygen via nasal cannula, rapid sequence induction with ketamine, suxamethonium, and halothane? Then add to that decision the reality that the anesthetic provider may be a nurse with 1 year of training in anesthesia, only 250 mL of compatible blood is available in the hospital, and there is no pediatrician to resuscitate the baby. What is the safest anesthetic technique? It is difficult to answer that question, but for anyone planning to work in an LMIC as an anesthetic provider it is indispensable to learn about the local resources, to listen to the local providers, to have the humility to not have all the answers, but above all to focus on the care and safety of the patient.

GLOBAL HEALTH COMPETENCIES

Although the number of global health opportunities for medical trainees has skyrocketed in recent years, most are short-term, elective-based rotations, and relatively few programs offer structured training in global health competencies.[237]

Although many anesthesia providers may not be directly involved with formal global health initiatives or careers that focus on underserved populations, there are fundamental global health competencies that are relevant to all anesthesia providers (whether in high, middle, or LICs). A broad understanding of key concepts is universally relevant and should be incorporated into anesthesia training for all providers. These include access and affordability, local and global disease burden, structural and social determinants of health, medical ethics, health equity, and social justice. The Consortium of Universities for Global Health (CUGH) has identified 11 competency domains, with four levels of competency per domain (ranging from level I for all providers with any relation to global health, to level IV for providers planning to have significant lifelong engagement in global health) (Box 2.5).[238]

For anesthesia providers who intend to spend a portion of their career focused on global health, additional training should be considered in topics such as: epidemiology, statistics, qualitative research, health policy, health systems, health economics, medical anthropology, demography, ethics, and implementation and management sciences, among others.

Providers from relatively well-resourced settings benefit from preparation before working in resource-constrained settings, even if only for short-term visits.[239] Several nonclinical challenges and pitfalls are routinely encountered in resource-constrained settings, including failure to provide context-appropriate interventions (see discussion on equipment donations in the section on infrastructure challenges), failure to have a follow-up plan, failure to adequately engage local stakeholders, overemphasizing short-term solutions, and draining local resources.[240,241] Certain ethical challenges are also commonly encountered and often relate to the appropriate scope of practice, the equitable distribution of local and external resources, and an inadequate understanding of local social and cultural norms.

In a survey of surgery and anesthesia trainees at a large Ugandan university with numerous visiting international collaborators, most trainees (75%) agreed that visiting groups improve their training. However, 40% of trainees reported that international groups had a neutral or negative impact on patient care. Only 15% felt that research

projects conducted by international groups were in local priority areas, and approximately one third of trainees (31%) reported discomfort with the ethics of clinical decisions made by visiting faculty.[242]

It is incumbent upon institutions that offer global health opportunities to provide formal training. Numerous resources exist to help equip trainees, providers, and institutions with the knowledge necessary to manage these challenges and maximize the positive impact of global health efforts (see the Appendix for links and useful resources).[243–246]

In some countries (e.g., the United Kingdom), anesthesia trainees can pursue 6-month to 1-year-long global health experiences, with formal curriculum and relatively long-term clinical, research, and educational components. Trainees are required to complete standardized assessments, including clinical evaluations and case-based discussions as outlined by the RCoA.[247] A relatively small yet increasing number of anesthesia programs in the United States and other countries are providing formal global health tracks for interested residents as well as formal anesthesia global health fellowships.[248] Academic institutions and the global anesthesia community at large must continue to expand training and career development opportunities that increase the number of anesthesiologists interested in and capable of improving equitable access to safe anesthesia worldwide.

Conclusions

Despite dramatic changes in anesthesia around the world over the past century, improvements in safety, access, and affordability have not been universal. At present, the majority of the world does not have access to safe anesthesia, surgical, or analgesia services, and relatively few resources are being devoted to address this growing crisis. The massive and growing surgical and pain crises disproportionately affect LMICs, where severe shortages of workforce and infrastructure, and impractical international regulations limit access to care. Despite many common misperceptions, anesthesia, analgesia, and surgical services are feasible in resource-constrained settings and are as cost-effective as many other public health interventions (e.g., vaccinations).

The neglect of pain and surgical disease by the global health community has resulted in one of the most inequitable global public health crises the world faces today. It has been only in recent years that the surgery, anesthesia, and global health communities have accelerated investment in research, education, and advocacy initiatives that aim to improve access to safe anesthesia and surgical services for the world's poor. These efforts are in their infancy and must be expanded and supported by the global anesthesia community. Factors affecting access to care, safety, and cost are relevant in all countries regardless of income level. All anesthesia providers should maintain awareness of the fundamental challenges facing the global anesthesia community, with the hope that increasing numbers will devote their careers to addressing issues of global health equity. There are many different ways for anesthesia providers to engage in global health at the patient level or system level, including research, advocacy, education, and clinical service.

The role of anesthesia in global health is easy for many to overlook, but the global anesthesia community must quickly increase efforts to actively lead global health initiatives that aim to improve infrastructure, expand workforce, increase translation of data into policy and practice, improve financial risk protection mechanisms for surgical patients, expand referral and prehospital systems, provide essential medicines, and ultimately improve access to safe and affordable anesthesia, surgical, and pain services worldwide.

Acknowledgments

The editors and publisher would like to thank the following collaborators for their contributions to this ever-evolving chapter: Maria Carmona, Deepak Tempe, Naoyuki Hirata, Michiaki Yamakage, Anis Baraka (deceased), Fouad Salim Haddad (deceased), Yury Polushin, Olga Afonin, Guillermo Lema, Florian Nuevo, Lars Eriksson, and D.G. Bogod.
This chapter greatly benefited from the contribution and thoughtful editing of Michael Cooper, Maytinee Lilaonitkul, Fred Bulamba, Cephas Mijumbi, and Doruk Ozgediz.

3 Perioperative Medicine

NEAL H. COHEN, MICHAEL A. GROPPER, and AMAN MAHAJAN

KEY POINTS

- The practice of anesthesiology continues to evolve with health care for patients undergoing new and, in many cases, more complicated procedures in the operating room as well as minimally invasive or interventional procedures performed in other nonoperating room settings. With the rapid growth of nonoperating room anesthesia, traditional operating room anesthesia care no longer dominates most anesthesia practices.
- The number of anesthesia subspecialties has also increased to include pediatric, cardiothoracic, obstetric, neuroanesthesia, critical care medicine, acute and chronic pain management, palliative care, and sleep medicine. Anesthesiologists' skills and expertise in subspecialties have grown paralleling the respective surgical specialties.
- The diversity of anesthesiology skills and clinical capabilities has created opportunities for anesthesiologists to take advantage of the changing healthcare environment and assume a more expansive role in perioperative care in both hospital and nonhospital settings, providing management of patients through the continuum of the perioperative or periprocedural period, and extending to home care and other settings.
- With changes in healthcare delivery, anesthesiologists will have to not only reassess current practices, but also define ways to adapt to new models of care. New approaches to care, while exciting for the specialty will be challenging to implement. While expanding the scope of practice, anesthesiologists must also continue to fulfill the traditional operating room roles and maintain the commitment to safe and high-quality intraoperative anesthesia care.
- To successfully transition to these new models of practice, anesthesiologists must acquire a more comprehensive understanding of the economics of health care and the role their perioperative care has in determining costs of care, outcomes, quality, and safety.
- The electronic health record and access to big data can serve as valuable resources in identifying opportunities to advance care and improve quality. To use the electronic record effectively will require that anesthesiologists acquire skills in biomedical informatics and data sciences to advance perioperative care.
- Public and private insurers are implementing new payment models to replace traditional fee-for-service payment for clinical care. They are transitioning from fee-for-service to "value-based" payment methodologies that better align quality, costs, and goals of care. At the same time, both government (e.g., Medicare) and private payors (e.g., insurance companies) are implementing new alternative payment models including bundled (fixed) payment methodologies designed to transfer the financial risk from patients and payors to providers, both physicians and health systems. Anesthesiologists must understand these new payment models and how they will impact clinical management and compensation for anesthesia services, particularly as anesthesia services and perioperative medicine evolve.
- Providing optimal perioperative care in the current healthcare environment requires implementation of new and creative models of value-based care that encompass the patient's entire clinical course as well as development of new partnerships and collaborations with other providers across the healthcare system. Anesthesiologists are well positioned to take a more prominent role in perioperative management, integrating their understanding of the surgical and medical needs of patients during and after surgical procedures. Concurrently, other physicians, including hospitalists, are partnering with surgeons to optimize perioperative inpatient care. Collaboration with hospitalists, medical specialists, and others is critical to improving perioperative care and in clarifying the roles anesthesiologists can play in providing value-based perioperative care. For some patient populations, co-management agreements can be executed to coordinate perioperative care and optimize transitions through the continuum of care.
- A variety of models for perioperative medicine are being successfully adopted in the United States and other countries. The perioperative surgical home (PSH) and Enhanced Recovery After Surgery (ERAS) protocols are examples of new approaches to collaborative multidisciplinary care that have demonstrated significant benefit for a number of patient populations—aligning goals for patients, providers, hospitals, and payors.

Introduction

The primary focus of anesthesia practice has traditionally been on the intraoperative management of patients undergoing surgical procedures in hospitals or ambulatory settings. Over the past few decades, anesthesiologists have been acknowledged for the significant improvement in perioperative safety and quality.[1] As a result of advances in anesthesia care as well as surgical and diagnostic capabilities, anesthesia services have expanded to include a wide variety of hospital-based and ambulatory settings outside of the operating room. While the diversity of anesthesia services has expanded, the basic elements of anesthesia care remained relatively consistent—preoperative assessment, intraoperative management, and postoperative care provided to ensure safe transition through the perioperative period. With increasing subspecialty training opportunities and changes in healthcare delivery and payment, new opportunities have developed for anesthesiologists to assume a broader role in both perioperative care and management of patients in the operating room and beyond. At the same time, the increasing capabilities and high costs of health care, particularly in the United States, is undergoing significant pressure to improve quality and safety while delivering value-based care consistent with patient wishes.[2,3] The changes create opportunities for anesthesia practices to evolve and for the role of anesthesiologists to extend beyond current clinical practices.

This chapter reviews the changes taking place in healthcare delivery and financing that create challenges and opportunities for anesthesiologists to expand their practices to incorporate concepts of perioperative medicine.

THE ANESTHESIOLOGIST AND PERIOPERATIVE MEDICINE

Perioperative medicine is an evolving field that focuses on optimizing the health and healthcare delivery of patients who will be undergoing surgery, and providing medical care for those patients following surgery. Anesthesiologists are well suited to advance their role as specialists in perioperative medicine and provide better care for surgical patients. New anesthetic techniques, monitoring capabilities, and evidence-based approaches to perioperative management have made anesthesia safer and improved the quality and safety of perioperative care.[1] Advances in surgery and development of minimally invasive techniques have had major impact on how anesthesia care is provided and expanded the locations in which anesthesia services are needed. At the same time, in part as a result of these changes, the patient population presenting for anesthesia has changed. Patients with significant underlying medical conditions who in the past were not considered candidates for surgery are now able to undergo complex surgical procedures successfully. These changes have had major impact on health systems, significantly increasing complexity and costs of care, while also putting pressure on healthcare resources including hospital bed capacity.[4,5]

For anesthesiologists, the advances in care, diversity of patients requiring anesthesia services, and the high costs of care create both new opportunities and challenges. Most significant to the practice of anesthesia has been the expansion in scope of clinical responsibilities in perioperative care of patients beyond the traditional operating room roles, and the need to improve operational efficiency in perioperative/periprocedural care and reduce costs. The challenges also provide the opportunity for anesthesiologists knowledgeable about operating room management to assume health system leadership roles and improve healthcare delivery for the surgical patients.

The change in scope of anesthesia practice is related to a number of different factors. The extension of anesthesia care to other inpatient and outpatient settings is based on management strategies and lessons learned in optimizing care in the operating room. The expansion of anesthesia services to interventional radiology, endoscopy, and cardiology suites has resulted in improved clinical management and, in some cases, better throughput.

Anesthesiologists have also modified clinical practices to optimize clinical care and improve efficiency. For example, preoperative assessment has been refined to improve clinical outcomes, but also reduce costs associated with laboratory testing and other preoperative testing that add no value.[6,7] At the same time, anesthesiologists have had a greater role in optimizing patients prior to surgery. Preoperative *management* of patients with underlying medical conditions, including diabetes, cardiopulmonary disease, and renal insufficiency, has improved the perioperative course and minimized the likelihood of postoperative complications. In some cases consultation with other medical specialists is required, but for most patients, the anesthesiologist's role is critical to optimizing the patient's conditions preoperatively as they best understand the interplay of the various perioperative variables including patient factors, anesthesia, and surgical techniques. As a key aspect of optimal perioperative medicine, anesthesiologists are able to provide postoperative management, including critical care and pain management for many of these patients based on their individual preoperative risk assessment and intraoperative course. In many respects, these changes have redefined anesthesia to encompass perioperative medicine.[8]

The expansion of anesthesia training in multiple subspecialties, as well as critical care medicine and acute and chronic pain management, also provides advanced and diverse skills that allow anesthesiologists, in collaboration with the surgical specialists, to ensure a coordinated approach to perioperative management. As a result, many anesthesia subspecialists have successfully expanded their roles in perioperative care. As one example, transplant anesthesiologists (also see Chapter 60) are often involved in discussions about patient selection, preoperative optimization, and transitions of care from the operating room to the postoperative period. Based on the collaboration of anesthesiologists, transplant surgeons, and medical specialists, anesthesiologists participate in selection discussions to provide their perspective on the perioperative implications of transplantation. For many transplant services, collaboration with the anesthesiologists has resulted in reengineering of care. Many patients who previously required postoperative care in the intensive care unit (ICU) can now bypass the ICU and have reduced hospital lengths of stay.[9] Similar outcomes have been documented for patients who have anesthesiologists participate in their perioperative management for cardiac surgery (also see Chapter 54), pediatric surgery (also see Chapters 77-79), neurosurgery (also see Chapter 57), or other subspecialties. In each of these examples, collaboration among the surgeons, anesthesiologists, and the overall team of providers both within and beyond the operating room environment is critical to realizing improved outcomes and reduced costs of care.

Anesthesiologists with advanced training in pain medicine and critical care are able to facilitate and optimize perioperative management. Pain management strategies have significant positive impact on the care of patients with both acute and chronic pain (also see Chapters 51, 80, and 82). Employing multimodal approaches to perioperative pain management, particularly for patients with longstanding chronic pain, perioperative pain medicine teams have had positive impact on perioperative outcomes, including reduced need for opioid analgesics and in some cases shortened the length of stay in hospital and improved patient satisfaction.[10-12] Similarly, critical care anesthesiologists play a large role in improving perioperative management of patients requiring ICU care. The value of the critical care physician on ICU utilization in reducing complications of mechanical ventilation, providing early diagnosis and treatment of sepsis, and improved management strategies for patients with renal dysfunction are well documented (see Chapters in 80, 84, and 85).[13-15]

An equally important factor contributing to anesthesiologists assuming greater responsibility in perioperative management is related to their knowledge of the overall perioperative environment, its complexities, and associated high costs. Advances in anesthetic management have facilitated implementation of new surgical techniques and allowed patients previously considered poor risks to undergo complex surgical procedures with good outcomes. These advances in care have contributed to the escalating cost of health care, particularly in the United States.[2] Not only are the high costs specifically related to the procedure, there are often substantial additional costs associated with complications of care, postdischarge care, and readmissions.[16,17] Anesthetic management has impact on costs of perioperative care, hospital length of stay, need for prolonged postoperative ICU stay, and other clinical outcomes. For example, intraoperative management can contribute to postoperative complications, such as pressure ulcers, central line infections, renal failure, aspiration and ventilator-associated pneumonia, cognitive dysfunction, and other complications. When these complications occur, hospitalizations are lengthy and rehabilitation (skilled nursing, physical, and rehabilitation services) needs are significant.

The need to address costs associated with managing complications of care is taking on greater importance. Over the past few years in the United States, government and private payors have raised concerns about the costs associated with managing complications of care, some of which are relevant to anesthetic management. These payors are reducing payment for costs associated with complications and denying payment for costs associated with readmissions.[18,19] As part of perioperative medicine, anesthesiologists have to identify these perioperative risks and, when clinically appropriate, identify ways to modify management to improve outcomes and reduce costs.

Another factor that has precipitated a need to address perioperative care in a more coordinated manner is the impact of changes in payment methods being implemented by both government and private payors as a way to control costs of care. In the United States, the primary method of payment to physicians remains fee based. While the implications of fee-for-service (FFS) payment methodology on quality of care and resource utilization are widely debated, FFS payment models are associated with overuse of some services, higher costs, and poor coordination of care.[20] In response to these issues, a number of alternative payment models (APMs) have been implemented including bundled payment methods and incentive-based payments associated with reduced costs of care and penalties when costs remain high. Under the Medicare Access and CHIP Reauthorization Act of 2015, Medicare has implemented a number of APMs and a Quality Payment Program that includes a Merit-Based Incentive Payment System (MIPS), each designed to compensate physicians for improving patient outcomes at reduced cost.[21] Medicare is also encouraging development of accountable care organizations (ACOs) in which health systems assume clinical and financial responsibility for managing a population of patients, improving quality, and reducing overall costs.

These changes in care management and payment methodologies have significant impact on all physicians and health systems. They shift responsibility and risk to the providers and are forcing physicians and health systems to implement value-based care. Anesthesiologists are knowledgeable about the complexities associated with perioperative care and have the ability to manage many aspects of the care and systems needed to optimize it. Consequently, they can help define new models of care and extend their role and assume greater responsibility for managing the perioperative course of some patient populations. For example, if anesthesiologists can help reduce costs during the course of care for a surgical patient, they can benefit financially under bundled payment methodologies, shared savings plans, and when participating in ACOs. Although issues related to payment methodologies are very different from one country to another and are beyond the scope of this chapter, the goals and implications of these newer payment methodologies should be understood by all anesthesiologists, since they have significant implications on the practice of anesthesia and the role for the anesthesiologist in perioperative medicine broadly.

While anesthesiologists are well suited to positively impact perioperative care, anesthesiology departments will need to adjust their focus and priorities to be better engaged in perioperative medicine. When provided in a coordinated way, perioperative care is cost effective and improves outcomes.[22] At the same time, the expansion of anesthesia practices, diversity of roles and responsibilities, and the subspecialization of anesthesia care have in some ways compromised the ability of anesthesiologists to fulfill their potential as perioperative providers. Compartmentalization of perioperative care and subspecialization have the risk of fragmenting care and undermining the development of a coordinated approach to perioperative management. At many hospitals, preoperative care is now provided in a dedicated preoperative evaluation clinic, physically separate from the operating room or other clinical sites. The evaluation is performed at some time prior to the surgical procedure; communication about the patient's status and clinical plans is most often done electronically with no face-to-face dialog or communication with the anesthesiologist who will deliver care during the procedure. Operating room care is provided by an anesthesiologist either personally or as part of the anesthesia care team model. Postoperative management—including care in the postanesthesia care unit, pain management, and ICU care—is often provided by another set of care providers. Perioperative medicine requires collaboration among all anesthesia providers, incorporating the knowledge and skills of each of the participants, including those providing preoperative management, intraoperative care, critical care, pain management, and so on. As much as each of the providers is critical to the care of the patient, the coordination of care among the anesthesiologists as a group is also a critical element in optimizing care, understanding and fulfilling the patient's goals for care, and improving efficiencies.

Perioperative Management

Throughout this text, the role of the anesthesiologist in various aspects of perioperative management is discussed. Each component is critically important to the quality, safety, and costs of care. The overall approach to care from the time a case is scheduled until the patient has recovered from anesthesia and surgery and resumed normal activities should be of concern to the anesthesiologist. Just as anesthesia as a specialty is acknowledged for advances in safety and quality in the intraoperative case, it should extend its focus and responsibility to the entire perioperative period—coordinating assessment, management, and responsibilities with the surgeons, hospitalists, other physicians, and nurses. By optimizing each of them independently and then coordinating the care across the continuum, the benefits of providing perioperative medicine will be achieved—with improved clinical outcomes, safer care, and reduced costs.

PREOPERATIVE ASSESSMENT AND MANAGEMENT

Chapter 31 emphasizes the changing patient needs and role of the anesthesiologist with respect to preoperative assessment and management. The chapter provides a more comprehensive discussion. To summarize current practices, for most healthy patients, a formal preoperative assessment is usually not required.[6,7] In fact, anesthesia providers have been able to reduce preoperative testing and other costs through the implementation of evidence-based protocols to standardize preoperative management for many patients.[7] Rather than requiring a preoperative visit, laboratory testing, and radiologic studies, most patients now have a phone consultation, often performed by a nurse practitioner to assess preoperative status and perioperative needs, and to address a patient's questions or concerns. For other patients, particularly those with underlying medical conditions or complex comorbidities, a more comprehensive evaluation and preoperative management and optimization of underlying conditions may be required.[23] For this subset of complex patients, preoperative assessment and management are an integral part of the continuum of perioperative care for which the anesthesiologist has a significant role. In some cases, additional diagnostic studies, such as an echocardiogram or focused pulmonary function studies, may be helpful in determining how best to manage a patient during the perioperative period. In this situation, interpretation of the studies may be done in coordination with a consultant or physician who has provided care to the patient preoperatively and who will resume care after the procedure is beneficial. The preoperative anesthesiologist may require a formal consultation with another specialist, such as a cardiologist, nephrologist, or pulmonary medicine physician, although these are needed for only a select few patients. For those patients with significant underlying conditions that will influence the perioperative course, particularly the postoperative recovery, referral for additional preoperative management (prehabilitation) can be helpful in optimizing their clinical status prior to proceeding with a major surgical procedure.[24-26] For most patients, the specific management strategies required to optimize the patient for anesthesia and surgery are often best defined when input is provided by the anesthesiologist who is most knowledgeable about the impact of chronic conditions on perioperative care needs as well as the implications of anesthesia on underlying physiology.

INTRAOPERATIVE (INTRAPROCEDURAL) MANAGEMENT

A number of initiatives have been implemented in hospitals throughout the world to improve intraoperative management, minimize complications, and reduce costs. The implementation of checklists has been demonstrated to improve patient safety in the operating room (also see Chapter 5).[27-29] Similarly, the routine briefing (i.e., time out) before beginning a surgical procedure reduces the incidence of wrong-site surgery, facilitates communication among providers, and ensures optimal patient care.[30] Some hospitals and surgical services also conduct debriefings at the end of each surgical procedure to define what procedure has been completed, clarify the postoperative expectations for the patient, and ensure that all supplies and materials have been appropriately retrieved from the surgical field.[31] These initiatives have reduced complications during surgery and, in some cases reduced costs of care. For example, the British National Health Service instituted "The Productive Operating Theatre" to improve productivity and patient outcomes during surgical procedures.[32,33] The program includes both briefings and debriefings to identify critical issues during and after a surgical procedure. This process has reduced errors and facilitated the transition from the operating room after a surgical procedure. Operating room utilization has increased, turnaround times shortened, and waste reduced. Significant financial savings have also resulted from this effort. The National Health Service is implementing similar initiatives in other hospital settings, such as "The Productive Ward" to build on the success achieved in the operating room environment.[34] Anesthesiologists need to be part of such initiatives that ensure there is an integrated approach to management during the intraoperative periods in order to demonstrate a significant and sustained impact on outcomes.

POSTOPERATIVE MANAGEMENT

The transition out of the operating room represents another important opportunity for anesthesiologists to enhance the quality and safety advances achieved in the operating room and improve perioperative patient outcomes. Advances in anesthesia safety have been acknowledged by the Academy of Medicine (formerly the Institute of Medicine) of the National Academy of Sciences[1] and other groups as a result of better anesthetic drugs, new anesthetic techniques, and improved monitoring. Although the incidence of intraoperative complications has been dramatically reduced, complication rates in the postoperative period remain high. The impact of variability in anesthetic practices on postoperative outcomes—beyond the immediate postoperative period—has received increasing attention for both patients who remain hospitalized and those who experience unintended and often unrecognized sequelae of anesthesia and surgery after discharge. For example, after a surgical procedure requiring tracheal intubation, a significant number of patients experience postextubation stridor or dysphagia that may last for days. These findings compromise the ability to protect the airway, particularly during sleep.[35] Does the dysphagia contribute to postoperative pneumonia that may not become clinically apparent until after discharge? Similarly, the most common healthcare–associated infections are pneumonia and surgical site infection, supporting the concept that intraoperative management is an important determinant of postoperative outcome.[36] Many other intraoperative strategies also impact long-term outcomes beyond the immediate postoperative period. Three examples support this conclusion. First is the influence of intraoperative fluid and vasopressor management on postoperative metabolic status and renal function.[37,38] Second, intraoperative glucose control can have a major impact on wound healing.[39] Finally, and more recently, anesthetic management can influence postoperative cognitive dysfunction for both adults and children.[40,41] As a result of these findings, anesthesiologists have a responsibility and an opportunity to understand the causes for these and other complications. We need to understand how anesthetic management contributes to adverse outcomes and how we can modify both intraoperative and postoperative care to reduce them.

COORDINATED PERIOPERATIVE MANAGEMENT STRATEGIES

While each of the components of perioperative care have specific requirements and approaches to optimize management, improve outcome, and potentially to reduce cost, perioperative management strategies must be assessed collectively, often using evidence-based clinical pathways to ensure that the goals of perioperative medicine are met.[42,43] Anesthesiologists have the opportunity to address these needs. To achieve these goals, however, anesthesiologists must reassess current models of care and modify some practices. One critical challenge to effectively coordinate care is the complexity of the perioperative course and management. In most clinical situations, it is no longer possible, nor appropriate, for a single anesthesia provider to participate in all aspects of the perioperative course. Perioperative, intraoperative, and postoperative care are often provided by different anesthesiologists, including pain medicine and critical care anesthesiologists in selected cases. To optimize perioperative management under this model requires improved communication and collaboration *among the anesthesia providers* as well as with others who participate in a patient's care. For some patient populations, such as geriatric patients or those with complex comorbidities, co-management agreements with other specialists can be executed to optimize care across the perioperative continuum, while clarifying roles and responsibilities.[44] The electronic health record is a valuable source of clinical information, but cannot substitute for more direct communication among providers, particularly in the management of complex clinical problems (also see Chapter 6).

The collaborative approach to care may not seem essential for healthy patients undergoing straightforward procedures. However, the value and opportunities for anesthesiologists to take a larger role in perioperative care is clearly evident for almost all patients—and the coordinated approach is appreciated by patients who are often confused about who is managing their care.[45] For example, patients undergoing "simple" procedures often have postoperative clinical issues that are underrecognized and require assessment and management. Anesthesiologists, surgeons, and nurses provide patients with instructions and information to help them manage their postoperative course, often at a time when they are not able to understand or process the information. As a result, even in these cases, the anesthesiologist can be instrumental in addressing postoperative anesthesia-related problems and coordinating the transition of the patient's care back to the primary care provider. The surgeon can provide information about the surgical procedure by forwarding the operative note to the primary care provider, but it rarely addresses any issues related to anesthetic management, concerns about the airway or potential for airway obstruction, or sequelae related to anesthetic agents, narcotics, muscle relaxants, or regional anesthetic blocks. In many cases, a phone consultation or teleconference is sufficient to address clinical needs. In other cases, a formal postoperative office visit may be required, as some anesthesia practices offer. Expansion of the postoperative assessment and management can be very helpful to patients, the surgeons, and other providers at the facilities to purvey a level of support to the patients that is often unavailable. The adoption of information technology resources and continued evolution of medical informatics (see Chapter 4) can enhance communication between patients and physicians during the entire perioperative period.

Besides the desire for a more coordinated approach to the entire perioperative course for every patient, a more formal and robust perioperative management strategy must be available for those patients with underlying medical conditions, those undergoing complex surgical procedures, and those needing prolonged hospitalization. In addition, for patients who require skilled nursing or rehabilitation services after discharge and for those needing home health services, the transitions of care create challenges for ensuring that postoperative management strategies are maintained, responses are assessed, and therapy is modified as needed. By its very nature, perioperative care for these patients is collaborative, requiring input and expertise from a number of different disciplines, including, but not limited to, anesthesia subspecialty expertise, surgeons, and medical subspecialists. Diverse perspectives and clinical expertise are essential, particularly for the more complex procedures in patients with multiple comorbidities. At the same time, the coordination of care must be assumed by a provider who is able to integrate the diverse perspectives into a comprehensive plan of care consistent with each patient's needs and goals. In the distant past, this coordination was provided by the patient's primary care provider, who maintained a role throughout the perioperative period. With the increasing complexity of perioperative care, changing demographics, and need to provide more efficient and coordinated care to reduce overall costs, the anesthesiologist has the opportunity to assume a more involved role in the management of some of these patients. To do so will require the commitment of the anesthesia practice to this new model of care and, in many cases, the acquisition of new clinical and management skills to deliver optimized care that is efficient and consistent with patient expectations.

One of the most prominent barriers for an anesthesia department to assume a greater role in perioperative management is its own members. It is imperative that there be consensus from all members of the department that a coordinated strategy is important and consistent with their expectations. To achieve department support, it is vital to clarify that perioperative management is a comprehensive approach to care that involves a diverse group of providers. Every member of the group must participate in the overall commitment to perioperative care. The care will be provided by a number of different anesthesiologists, each with different clinical expertise. One example of this coordinated approach to perioperative care is the management of a patient with a history of chronic severe pain who undergoes a complex surgical procedure. The patient will undergo extensive evaluation and optimization of care in the preoperative evaluation programs. Intraoperative care will be provided by another anesthesiologist, one who has communicated with the patient and understands all of the clinical issues identified and addressed preoperatively. When the patient is transferred to the ICU for postoperative care, which includes ventilator support, intensive respiratory care, hemodynamic monitoring, and fluid management, the transition from the anesthesiologist who provided intraoperative care to the critical care anesthesiologist is seamless. Pain management is provided by the pain service in collaboration with the critical care anesthesiologist (also see Chapters 51 and 82). The remainder of the patient's course of care will be managed by a member of the anesthesia department to facilitate transition to another care facility or home, and to ensure effective communication with the primary care provider or other caregivers. Although this model is foreign to many practices, it represents one of many approaches to optimizing perioperative management and takes advantage of the expertise of anesthesiologists in the overall care of the patients they anesthetize.

Finally, new approaches to perioperative management also require that each practice acquire the necessary operational, clinical, and financial data, as well as the analytical capability to interpret it. Larger regional and national organizations have the broad expertise available to analyze the practice and determine where improvements in processes can benefit patients and enhance the efficiency of the practice. For smaller practices, it can be challenging to have this broad level of expertise and access to information, although some have very successfully incorporated these strategies. As a consequence, in the United States there has been considerable consolidation of anesthesia practices by large regional and national organizations.[46] This consolidation has enabled the larger, often multi-institutional group to provide the resources needed to help anesthesia practices optimize perioperative management and document the value of the anesthesia services from both a clinical and financial perspective. Some groups have transitioned to multispecialty groups or recruited hospitalists or other providers to the anesthesia practice to supplement the clinical skills of the anesthesiologists so that the department has the diverse clinical and management expertise needed to optimize perioperative care. This multidisciplinary approach to perioperative care enables the group to expand its scope of practice and to develop clinical and administrative databases that allow them to document the value of their services to both patients and the institution. From an administrative perspective, this strategy better positions the practice to negotiate with representatives from the hospital or health system, particularly when advocating for the share of bundled payments. Because the administrative and analytical capabilities are essential to optimize delivery of perioperative care, each practice of whatever size will need to identify the most effective ways to develop this expertise and acquire the data needed to successfully address the many challenges facing anesthesia practices.

Models of Perioperative Care

Most health systems and providers are challenged to identify ways to become more efficient and reduce costs while maintaining or improving the quality of care, particularly perioperative care. Accomplishing these diverse goals is difficult and no single model of care works for every patient population or healthcare setting. As a result, many approaches to delivery of perioperative care have been implemented, some of these successful and some for which the outcome remains unknown. Although models of perioperative management include the anesthesiologist, other providers have participated in the preoperative and postoperative management of complex patient populations, each with variable success. Based on these experiences, the key aspects for any model for perioperative management include: (1) an understanding of the specific patient population included in the model (e.g., specific surgical procedure), (2) sufficient clinical and financial information to allow evaluation of the management strategies and their implications, and (3) coordination and collaboration among all providers participating in the model.[47] As models for perioperative management have evolved, they have taken advantage of the experiences from the hospitalist model for inpatient care and the medical home model for chronic disease management.

PATIENT-CENTERED MEDICAL HOME

The medical home model, also referred to as the "patient-centered medical home" (PCMH) refers to the model of care in which a primary care physician provides comprehensive care to improve health outcomes for a population of patients.[48] The critical element of the PCMH is the coordination of care to reduce emergency room visits and hospitalizations. In managing the patient population, a number of strategies are implemented to reduce costs and improve outcomes. These models often utilize additional providers, including advance practice nurses, respiratory therapists, physical therapists, and patient advocates to manage chronic diseases such as asthma, chronic obstructive pulmonary disease, heart failure, and diabetes mellitus. Payment for the PCMH includes FFS payments for episodes of care as well as payment to coordinate care. This model has been successful in improving care, particularly for patients with selected chronic diseases, although the financial success has not been consistently achieved.[49-51] In some cases, the PCMH actually resulted in increased hospital admissions.[52] Despite the variable success of the PCMH, there are some lessons that can be applied to perioperative care. First, preoperative assessment must be comprehensive enough to identify underlying clinical problems and effectively manage them, both preoperatively and postoperatively (also see Chapter 31). For the anesthesiologist managing the perioperative period, chronic conditions must be addressed; the management of these cannot be deferred to other providers. The implications of the perioperative needs must be taken into account when managing chronic diseases during the course of surgical care. Second, the underlying medical conditions must be considered as part of the proposed procedure and its implications for postoperative management. This broader perspective requires coordination with the surgeon and for some patients, the hospitalist, other specialists, and the primary care provider. For example, a patient with peripheral neuropathy associated with diabetes mellitus may be unable to participate in traditional approaches to rehabilitation; care must be tailored to the specific needs of each patient in consultation with others who can modify care as needed to optimize likelihood of achieving the desired outcome. Third, while participation by anesthesiologists is essential, many aspects of perioperative care can be managed by other providers, including other physicians and advance practice nurses. The keys to successful perioperative management, however, require that there be a single physician responsible for coordinating care among the team of providers, ensuring consistent and ongoing communication about patient care needs, and the availability of data that can be used to analyze clinical and business practices, costs of care, and outcome measures. The responsible provider during the perioperative period may be the anesthesiologist, surgeon, or hospitalist. As the patient recovers, the responsible provider may transition to the primary care provider, as long as there is good communication and appropriate "hand-off."

SURGICAL HOSPITALIST

Another model that has been implemented in many hospitals in the United States and other parts of the world is the surgical hospitalist model, which builds on the hospitalist model of care for inpatient medical patients. Many studies have documented the clinical values and other advantages associated with implementation of a robust hospitalist program.[53,54] Most of the programs have been focused on the care of patients with acute (and perhaps underlying chronic) medical problems rather than patients undergoing surgical procedures. For the surgical patient, the role of the surgeon is evolving for a number of reasons: the percentage of surgical inpatients is increasing, and inpatient clinical needs are becoming more complex and difficult for the surgeon to manage without additional support. As a result, many hospitals are recruiting hospitalists to provide perioperative care for surgical patients.[53,54] In some cases hospitalists work with specific surgical services (or an individual surgeon) to manage overall care and transitions of care into and out of the hospital environment. The models for surgical hospitalist programs vary, in some cases incorporating hospitalists with primary training in internal medicine or pediatrics, and in some cases, having a surgeon with interest in perioperative care take on the hospitalist role. In each model, the clinical management issues are similar, though the knowledge and skill to manage patients with complex comorbidities may differ considerably.

Many of these surgical hospitalist models have been successful in optimizing care of both underlying medical conditions and perioperative needs related to the surgical procedure. Although there is limited experience to document the effect on hospital lengths of stay and readmission rates, the models have been effective at improving timeliness of interventions, and patient and staff satisfaction.[54] For this model to be most effective requires that the surgical hospitalist be knowledgeable about the idiosyncrasies of perioperative management related to the specific surgical procedures. Their effectiveness is most evident when the care of underlying medical conditions is carefully coordinated with the other perioperative needs of the patient. For example, the neurosurgical hospitalist must understand concepts such as cerebral autoregulation and the impact of clinical interventions on cerebral hemodynamics for the patient who has undergone a neurovascular procedure. Similar considerations must be addressed for hospitalists working collaboratively with other surgical services.

The surgical hospitalist model has been very effective in allowing surgeons to concentrate their efforts in the operating room. However, the optimal relationship between the surgical hospitalist (whether a surgeon who has assumed this nonoperative responsibility or a medical hospitalist) and anesthesiologist during the immediate perioperative period has not been standardized. In some cases perioperative care is transferred from the anesthesiologist to the hospitalist in the immediate postoperative period; in other cases, care may be transferred from the anesthesiologist to an intensivist (either a critical care anesthesiologist or another intensive care physician) while the hospitalist maintains responsibility for managing some of the underlying clinical conditions. In the latter case, the roles and responsibilities of the anesthesiologist, critical care provider, and hospitalist need to be clearly defined to ensure appropriate coordination and transitions. Either model can be effective when coordination of responsibilities is clearly delineated. Another important component in the perioperative care of the patient is the transition from the inpatient to outpatient setting. When possible, there should be good communication and coordination of the transfer of care to the outpatient physician who is provided sufficient information about the intraoperative course and its implications, including any issues that arise as part of the anesthetic management that might impact postoperative management.

ENHANCED RECOVERY AFTER SURGERY

Enhanced recovery after surgery (ERAS) is another example of a creative approach to the perioperative management of patients who undergo major surgical procedures.[55,56] ERAS protocols are evidence-based pathways designed to improve care and outcomes as well as efficiency in the perioperative period. ERAS protocols require a multidisciplinary approach to perioperative care with particular emphasis on the entire perioperative course. The most successful ERAS programs are the ones that include participation by all of the healthcare and service providers who have a role in the perioperative course for the patient population.[57,58] Most ERAS protocols include preoperative education, perioperative antimicrobial management, pain management strategies, and early rehabilitation. In some cases, separate protocols have been initiated to address each period in the perioperative course, one to address the immediate perioperative management strategies and another to concentrate on the patient-care needs outside of the immediate postoperative period.[59] Many successful ERAS protocols have been implemented to optimize care of patients undergoing a variety of surgical procedures, including laparoscopic and other colorectal procedures, breast surgery, and urologic surgery.[60,61] Recently an ERAS protocol was implemented to optimize perioperative management of living liver donors[62] and another designed to improve perioperative management of patients undergoing elective craniotomy.[63] Each of these protocols has resulted in improved patient outcomes. For some patients, hospital lengths of stay and postoperative complications were reduced by as much as 30% and 50%, respectively[64,65]; for others postoperative pain management was improved despite administration of less opioids.[60-62,66]

As noted earlier, one of the most important features of the ERAS program, as with other pathways designed to improve perioperative care, is that the protocols are developed by a multidisciplinary group of providers that includes physicians, nurses, respiratory therapists, and others to ensure seamless coordination across the continuum from preoperative, intraoperative, and postoperative (postdischarge) periods.[67] The anesthesiologists offer essential information about key components of anesthetic management that can be modified to improve outcomes.

The outcomes associated with implementation of ERAS protocols have generally been positive for patients, providers, and health systems. In addition, the implementation of the protocols with participation of all providers involved in patient care enables a comprehensive review of the clinical course and outcomes, costs, and resource needs. The participants should be encouraged to review the clinical, financial, and other data regularly and, if appropriate, to modify the protocol to optimize care. One protocol recently implemented to improve care in colorectal surgery identified an increased incidence of acute renal injury.[68] The patients at risk for acute renal injury were those who had longer operative times and an associated diagnosis of diverticulitis. The findings emphasized a need to reassess the management strategies and to implement a goal-directed approach to fluid management intraoperatively and postoperatively. Follow-up will be required to determine if these changes in the protocol will be successful. These findings, however, emphasize the need to not only work collaboratively during the development of the protocol, but also review the experiences after implementation and modify the protocol when adverse outcomes occur.

Based on experiences with many of the ERAS protocols initiated to date, this approach to refining and improving care has been successful in improving outcomes and lowering costs. From a healthcare economic perspective, the ERAS protocols represent a value-based approach to optimizing care.[55] The development of the protocols give anesthesiologists an opportunity to engage in discussions with surgeons and other providers involved in the patients' care about how to optimize perioperative care and how to modify anesthesia practice and pain management strategies to facilitate recovery and potentially reduce complications. At the same time, while the reported improvements in outcome are impressive, anesthesiologists and other providers should ensure that outcome measures of most importance to patients are incorporated into future ERAS protocols in order to enhance their value.[58,69]

PERIOPERATIVE SURGICAL HOME

The expanding roles identified for anesthesiologists provide the foundation and framework upon which they can take on even broader roles as perioperative physicians.[70-72] The American Society of Anesthesiologists (ASA) in collaboration with other medical specialties has developed the perioperative surgical home (PSH) as a model for coordinating care throughout the entire perioperative period.[73-75] Many of the concepts incorporated into the PSH are built on the same foundation as those incorporated into the PCMH model. The PCMH is designed to better manage patients with complex medical problems and comorbidities in the outpatient setting,[49-51] whereas the PSH emphasizes clinical management of the patient from the time of scheduling of a surgical procedure through the entire perioperative period. The PSH is designed to specifically optimize outcomes during and after surgery, and to facilitate the transition of the patient back to the primary care provider. As with PCMH, the concept of the PSH model is to provide patient-focused care, consistent with patient goals and expectations. The goal for the PSH is to develop evidence-based clinical pathways designed to improve outcomes, and reduce overall costs-of-care across the continuum, including costs associated with home care and skilled nursing facilities.[76] Although the goals for implementation of the perioperative surgical home are clear, there is no single model nor list of specific guidelines one can follow when implementing a PSH. For some PSH models, the anesthesiologist assumes primary responsibility, whereas in other cases the surgeon is the lead provider. For some PSH models, co-management agreements with other providers has facilitated coordination of care and resulted in fewer surgical cancellations, less complications, lower lengths of stay, and fewer readmissions. For many PSH experiences, even when the anesthesiologist assumes a major role in the overall care of planning and execution, input from other providers (including hospitalist or medical subspecialist) is obtained based on the clinical needs of the patient. The collaborative relationships that are developed under the PSH extend to the care of other patients and provide the opportunity for other providers to better understand the skills, roles, and responsibilities of the anesthesiologists. These relationships are also critically important in representing the value anesthesiologists have under bundled payment models.

Although the goals for the PSH and ERAS protocols have some similarities, the components and overall goals for the PSH are somewhat broader than the expected outcomes for ERAS protocols. As proposed by the ASA, the PSH has the following major goals:

- identify the patient and proposed plans;
- facilitate communication among the surgeons, anesthesiologists, and others as needed to coordinate care;
- provide thorough preoperative assessment and develop a care plan, including management strategies for associated diseases;
- develop and implement evidence-based protocols for clinical care throughout the perioperative period;
- manage clinical care across the continuum; and
- measure and publicly report outcomes and performance.

The fundamental components of the PSH are clearly desirable goals and build on many of the basic concepts of perioperative medicine. The PSH is generally more comprehensive, requires thoughtful leadership and institutional commitment beyond what is often required for an ERAS protocol designed to reengineer care for a focused surgical procedure.[76,77]

A number of examples of the PSH model have been successfully implemented for selected patient populations with impressive results.[78,79] Some are relatively straightforward evidence-based strategies to optimize perioperative care, whereas others are more comprehensive. The process for developing a PSH can be cumbersome and requires a great deal of coordination across both inpatient and outpatient settings and, in some cases, participation of different healthcare systems. The model requires a designated physician leader who has responsibility for overseeing the continuum of perioperative care. To implement a successful PSH requires that the physician champion have some training and experience in process improvement strategies.[80] The model also requires support from other providers, particularly surgeons and hospital administrators.[81] Although the PSHs have been implemented in a variety of healthcare settings, the most comprehensive models can be successfully implemented in "closed" healthcare systems, such as the Veterans Administration, Kaiser, and other fully integrated delivery models.[79,82-84] The implementation is more challenging when the PSH requires participation of providers and facilities from multiple different environments, as may be required for patients needing rehabilitation, skilled nursing, or home care.

Despite these constraints, the implementation of the PSH has been successful with improved clinical care, reduced costs, shorter lengths of stay, fewer hospital readmissions, and both provider and patient satisfaction. The fundamental components of the PSH are clearly desirable goals and build on many of the basic concepts described for perioperative medicine. The model has promise in addressing the challenges associated with care to patients with complicated medical problems who are scheduled to undergo a complex surgical procedure. How effectively this model can be expanded to address this broader patient population and engage more providers and health systems is still to be determined.[77,85]

Conclusion

Perioperative care continues to evolve, in large part because of the advances made in surgical and anesthesia management of patients undergoing complex procedures in the operating room and nonoperating room settings. Surgical procedures are now commonly performed on patients with underlying medical conditions that impact anesthetic and surgical management. At the same time, and, in part as a result of the changing patient population, the cost of care continues to escalate. Payors are concerned about the increasing costs of care and, in some cases, point to the lack of evidence to support some costly clinical practices. Medicare and some private payors are transitioning to MIPS with associated incentives for providing value-based care and penalties for poor performance.[86] At the same time, providers are being asked to assume greater risk by providing bundled payment for selected diagnoses. To address these dramatic shifts in payment and concerns about the overall costs of surgical care, new models of perioperative care and implementation of clinical pathways based on evidence have evolved. These new models of care require better cooperation and coordination among all providers. The concepts behind perioperative medicine provide the framework upon which to reengineer care to address these challenges. Although no single strategy is appropriate for all clinical settings and patient needs, the one critical component of perioperative medicine is the need to implement a model of care that ensures coordination, collaboration, and improved transitions across the continuum from preoperative assessment and management to postoperative rehabilitation. These elements provide the opportunity for anesthesiologists and anesthesia departments to expand their scope of practice, building on the successes in improving intraoperative quality and safety. A number of alternative approaches to optimizing perioperative care may be appropriate and in all likelihood, multiple strategies will be required to address the idiosyncrasies of each patient population, surgical procedure, and institutional capabilities. The PSH is an example of a new creative model that might have significant benefit for selected patient populations; aligning patient's, provider's, hospital's, and payor's goals; and significantly improving perioperative care by building on the experience and successes of other approaches including ERAS, the surgical hospitalist model, and the PSH. To successfully assume an expanded role, anesthesiologists will have to build on their clinical expertise, and will have to acquire and analyze data on outcomes and costs to document that the new models of perioperative care are fulfilling the needs of all providers, health systems, payors, and, most importantly, patients.

Informatics in Perioperative Medicine

DOUGLAS A. COLQUHOUN, NIRAV J. SHAH, and
SACHIN K. KHETERPAL

KEY POINTS

- Individual computers are connected via networks to share information across many users.
- Information security is about ensuring that the correct information is available only to the correct users at the correct time.
- Healthcare information storage and exchange is regulated to protect patient privacy.
- Information regarding the provision of anesthesia care is highly structured and organized compared to most healthcare specialties.
- Anesthesia care documentation systems have evolved in complexity and are now widely adopted in the perioperative care of patients in the United States.
- Benefits of electronic documentation of anesthesia care typically emerge from integration with monitoring, scheduling, billing, and enterprise electronic health record (EHR) systems.
- Active and passive decision-support tools may suggest typical courses of action or call to attention patterns that are not apparent to the clinician.
- Secondary use of EHR data is valuable in understanding the impact of clinical decisions on patient outcomes and the measurement of quality of care.
- Electronic devices may act as distractions within the operating room (OR) care environment.

Introduction

Computers have become ubiquitous in modern life. Their use has penetrated every medical field and the practice of perioperative care is no different. Computers have given rise to the academic discipline of informatics, the study of information creation, storage, handling, manipulation, and presentation. Within health care this is referred to as medical, biomedical, or clinical informatics.

Computer Systems

At their most basic, computer systems are complex electronic circuits that perform mathematical operations (add, subtract, multiply, divide, and compare) on information available to them. Even the most complicated computer systems consist of these operations repeated millions of times per second, which collectively generate the activity specified by the user. Every operation performed within the computer begins with the retrieval of information in the memory, a mathematical operation within the processor, and the storage of the output of that operation back to the memory. This cycle of retrieval, processing, and storage repeats millions of times per second.

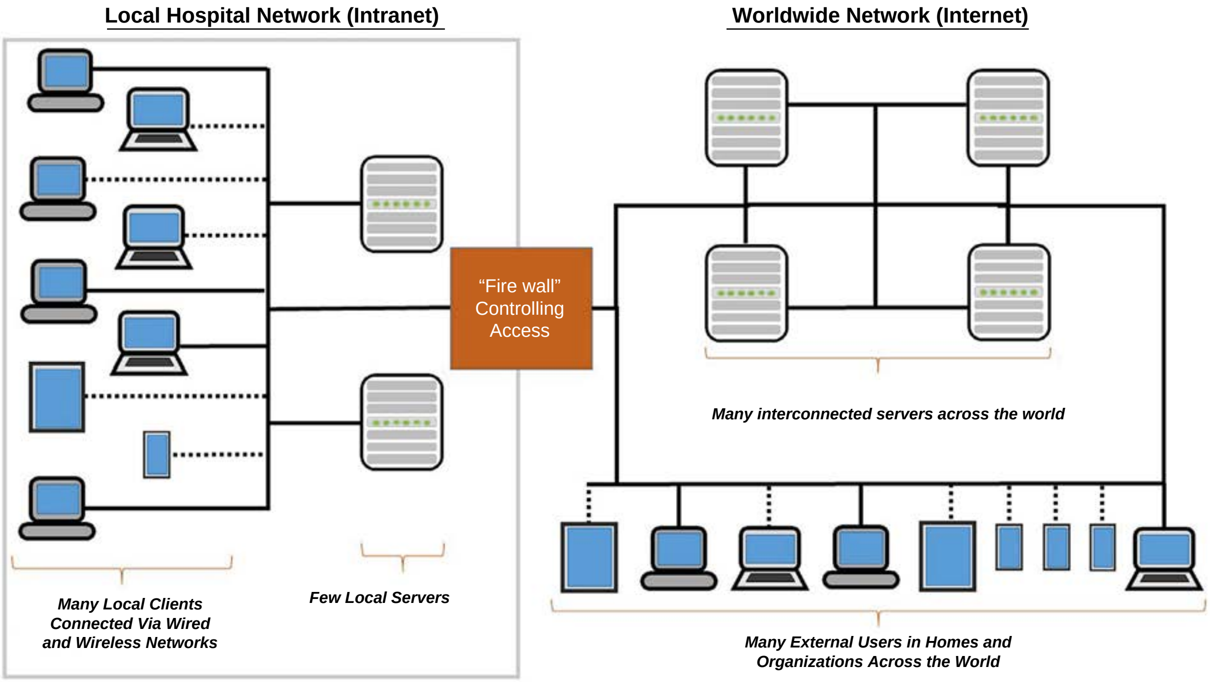
Software applications execute the instructions that a computer uses to process information. The operating system is the fundamental software that controls the communication among the components of the computer. The operating system controls the order in which a processor completes tasks, allocates memory among different applications, provides a structure for organizing files in the long-term storage, controls access to files, determines which applications may run, and manages the interaction between the user and the computer. Modern operating systems provide graphic interfaces that act as paradigms to describe the organization of information and methods of user-specified computer action.

A software application is a set of instructions for a computer designed to perform a specific set of tasks. Electronic health record (EHR) software is an example of a software application. Software may (via the operating system) interact with external hardware devices, data held in long-term storage, and the user by way of input devices and display devices.

Because of the proliferation of mobile devices, traditional laptop or desktop computer systems have been supplanted in many environments by tablets or smartphone computers. These devices are structurally similar to traditional computing devices; however, the operating systems and software applications feature user interfaces that have been re-engineered to support use by touch screen or voice control operation. These devices trade off computational power, portability (size- and weight-related), and duration of operation (battery power).

Computer Networks

Networks are the means for the exchange of information among computers, enabling the sharing of resources. These networks may be established using wireless (e.g., microwave radio spectrum) or wired connections (Fig. 4.1). Dedicated hardware (equipment) controls the sending and receiving of information across these links, with specialized devices required to ensure that information is sent correctly



Local Hospital Network (Intranet)
Worldwide Network (Internet)
"Fire wall" Controlling Access
Many interconnected servers across the world
Many Local Clients Connected Via Wired and Wireless Networks
Few Local Servers
Many External Users in Homes and Organizations Across the World

Fig. 4.1 Relationship between a local intranet (within an institution) and the wider Internet. Institutions may choose to use an external vendor to provide certain services hosted on external servers, this is referred to as "cloud" computing or services. Prevention of unauthorized access to the intranet from external parties while allowing users to access the Internet and other remote resources is of paramount concern. "Firewall" devices aid in the separation of the institutional network from the wider Internet and control access.

to the intended computers on the network. Software is used to ensure communication is performed according to predefined standards. In order for a computer to be accessible in the network, each computer must be given a unique address on the network so that information can be identified as destined for that computer. The process of obtaining and maintaining network addresses is performed within the local operating system and network hardware. This allows software applications to specify the information to be sent and the operating system and network hardware to manage how it is exchanged between computers.

Wired networks require the computer system and the receiving hardware to be physically connected by electrical or optical cable. This limits the flexibility in the connection points, which must be placed in preplanned areas, with any subsequent adjustments requiring re-routing of cables. However, information travelling on the network cannot be intercepted or accessed without physical access to the network cables or connection points.

Wireless network systems offer advantages of convenience and the ability to move around a work environment without maintaining a physical connection among the computer systems. However, this usually occurs at the expense of speed of information exchange. Information exchange via wireless links is an order of magnitude slower than the fastest wired connections. Because wireless systems require the availability of strong radio links between the computer and the network equipment, they are subject to issues of poor reception (possibly because of physical barriers) and interference, which manifest as inaccessible or degraded network performance. It is difficult to control the precise limits of where a wireless network is available (i.e., only within a building and not immediately outside of it), therefore processes to limit wireless network access to authorized users and to encrypt data transmitted across wireless links are required.

In practice, healthcare facilities use a blend of both wired and wireless networks to ensure that the advantages of each system are available to support the users.

In most settings, the network is organized as a "client-server" model. The computer that hosts the shared resources is referred to as the "server" and the computer accessing the resources is the "client." The server is responsible for ensuring the client is an authorized user of the shared resource (access control) and ensuring the resource remains available to multiple users, potentially by preventing one client from monopolizing the use of the resource.

The client-server concept stands in contrast to peer-to-peer architecture, whereby resources are distributed across systems, with each computer on the network contributing its resources (e.g., files or specialized hardware). All computers are both clients and servers in this arrangement. There is limited ability to control access in a planned and coordinated manner.

Use of a client-server infrastructure may allow for a significant amount of the computational tasks to be outsourced to the central server. When the client has very limited computational resources this is referred to as a "thin client." Computationally intensive tasks can be performed by the server and the client receives the results of the computation. Fundamentally, the thin client is viewing and interacting with a software application that is running on the server. The client is little more than a means of sending user input to the server and a dynamic display of application results. In order for this arrangement to work, there must be a limited, predictable set of software applications that the client accesses on the server, with a reliable network connection. Without the network connection, the thin client has no functionality. This model may be easier to maintain because any changes are done centrally and need to be made once and then become available to every client connecting in.

An alternative model is the "thick client," where the client is capable of significant computational activities, retains a fully functional state when not connected to the network, accesses only the information required across the network, and processes it independently. However, these clients require individual maintenance.

A hybrid solution is the concept of "application virtualization," whereby a single software application is hosted and uses the computational resources centrally and the client systems access this application regardless of their configurations. This blends the advantages of a thin client—control of the application's availability, ease of maintenance, and ensuring compatibility (by not requiring any level of computational resources aside from running the connection to the server)—with users having a fully functional computer or device to use for the remainder of their tasks. Additionally, this hybrid enforces a separation between the information stored on the server and any applications running on the client and thus information can be secured within the server that is housed within the institutional network.

The Internet

The Internet is a global network of networks. Best known by two of the ways in which it can be used—websites and email—the Internet is at its simplest a method for transferring electronic information across the world. Internet service providers (ISPs) provide access to optical and electrical cables, which transfer information across the world. As these cables are all interconnected, multiple paths are available to transfer data at any one time. Routers control the flow of Internet traffic and ensure that it takes the most direct and fastest routes across the multiple paths available to it. Although the delay that a user may experience in accessing information varies widely and is dependent on many factors, the flow of information around the world can be measured in the order of hundreds of milliseconds or less.

Use of the Internet has led to the development of a series of technologies where computing resources are offered to multiple clients using an Internet connection as a means of distribution and interaction with the clients (see Fig. 4.1). These "cloud" platforms allow on-demand and scalable use of computing resources. Computing resources can be bought and sold based on the variable amount of time they are used or the amount of information stored; additional capacity can be flexibly added. These resources are accessible from anywhere with an Internet connection. Furthermore, cloud platforms give organizations the ability to transfer the management of the specialized computer hardware needed to provide these services to another party.

The integration of mobile phone data networks and the proliferation of increasingly powerful handheld devices (such as smartphones or tablets) has increased further the number of potential clients. For healthcare organizations, there is significant user pressure to be able to access healthcare information systems remotely or from these mobile devices.

The most ubiquitous usage of the Internet is in the delivery of "web pages." Information is stored on a "web server" and upon request from an application being run on a remote client computer (web browser), the information and display formatting instructions (i.e., size, shape, position of text, or graphics) are sent to the client. The web browser then interprets these instructions and displays the information according to the specified instructions. This process is highly dependent on well-defined and accepted standards of information exchange between client and server and rendering by the client.

These web pages have become increasingly sophisticated incorporating text, video, audio, complex animations, stylesheets, and hypertext links. Technologies have evolved into an interactive process that can dispense information specific to only one user (e.g., a record of the user's bank transactions) and that can be supplied in a manner that is generalizable to many different users (so all customers can access their bank transactions this way). When these instructions are assembled to generate specific business processes, they function as software applications that are web based and are referred to as "web applications" or "web apps." Interaction with web pages may lead to complex business processes being undertaken in the physical world. For example, the ability to buy a book over the Internet starts with a web page displaying the information and ends in someone delivering it to the door, with many physical steps in between. Healthcare organizations have embraced these technologies to support their delivery and administration of patient care, including scheduling systems, laboratory result reporting, patient communications, and equipment management systems, all of which are delivered in this manner.

Of note, information which is travelling across the Internet, without additional measures, is not necessarily private. A salient metaphor would be to consider the difference between information being conveyed in an envelope (where the contents are not visible) and information being conveyed on a postcard (where the message is clear to anyone who holds it).

Information Security

Although computing technology has significantly influenced the delivery of medical care, it has also brought a series of challenges that must be addressed. A major consideration is information security. Core to these considerations is ensuring that the correct information is available to the correct users at the correct time.

These threats to information security may come from within or outside an organization. Within organizations, an employee may access information that they are not authorized to so do or by transferring and storing it in an insecure manner. They may introduce security threats by using applications that may transfer information outside of the organization or by modifying an existing network by using a personal device. External threats may seek to improperly access information ("hacking") by obtaining passwords or identities from legitimate users (via "phishing" attacks) or by introducing applications that degrade computer function to extort payment ("ransomware" attacks).

The paradigm used for controlling access to computing resources is users and accounts. Each person who uses the computer is considered to be a user. Users can be identified and mapped to real-world persons. Users may belong to groups that share common attributes. It should be known in advance which resources should be available to which users or groups of users. A group of users (i.e., anesthesia providers) may have access to particular resources (e.g., a document of anesthesia policies) but each user may also have access based on their individual parameters (e.g., an individual anesthesiologist may have sole access to his or her own private files). A group of users with similar functional roles who have a defined set of resource privileges is known as "role-based security." Changes in privileges affect all users in that functional group.

Users should be able to positively identify themselves; commonly this involves the combination of a username and password with the password being known only to the user and the computer system. However, other methods of authentication, such as biometric information (fingerprint, iris scan, or face scan) or physical access tokens (e.g., identification badges) are now commonplace. Password policies that enforce a mandatory level of complexity (minimum length, mixing letters and numbers, or special characters), specific expiry dates, and prevent password reuse are designed to make it harder for passwords to be guessed by an unknown party or to mitigate or minimize the risk of passwords being accessed or used externally. However, requirements for increasing complexity or frequency of changes may pose additional burdens on users that they consider unacceptable and may not decrease risk.

Organizations may also choose to adopt "two-factor authentication" methods, which can be summarized as requiring "something you know and something you have" to gain access to the computer system. The password fulfills the first part of this concept as it is meant to be known only to the user. Devices such as physical token code generators (which provide a predictable response to be entered alongside the password) or an interactive system (authentication via a smartphone application or phone call) may satisfy the second concept. Thus, in order for someone to impersonate the user they must have both the password (that may have been taken without the user's knowledge) and a physical device (that the user is more likely to detect the absence of). This makes remote access less likely because an external user on the other side of the world may be able to obtain or guess a password but is very unlikely to also be able to obtain the token or smartphone required for access.

Physical security is an integral part of information security. Ensuring that an unauthorized person does not have physical access to computer hardware or access to the means of connecting to that computer hardware are important considerations. This can be accomplished by physical measures (such as locked rooms, doors, and devices that prevent movement of computer hardware) and considerations of where computers containing controlled information are placed (to prevent an unauthorized person from having access to a computer that is available in a public area).

However, as alluded to before, these restrictions are balanced against desires for increased usability and portability of computing devices from computer users and the need to make information available to the provider at the point of clinical interaction.

Therefore, it is necessary to ensure secure access to information across wireless links and across the Internet. One method for doing this is to ensure that the information transferred is not readily visible along its means of transmission. This is performed by a group of processes known as encryption. Encryption is the process of transforming a piece of information from its original and accessible state to one that is not accessible and lacks meaning without an additional piece of information (an encryption key).

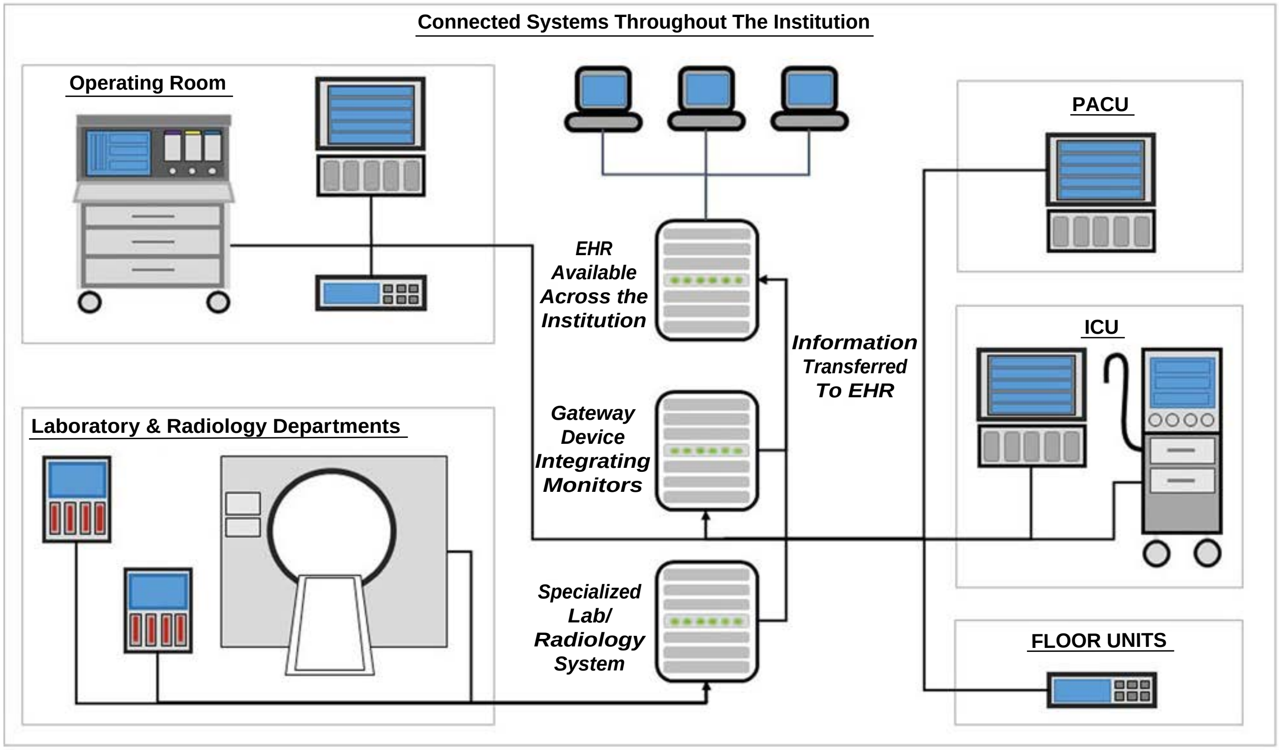
The transformation to and from encrypted text takes place in a manner that is relatively easy to perform with the known encryption key but is infeasible to do so without knowing this key. Encryption processes are based on mathematics involving multiplication of very large numbers, which creates many possible combinations of different factors that could have led to the same outcome. Therefore, it would be computationally infeasible, with current technology, to attempt to try all possible solutions.

External threats to an organization involve outside entities attempting to access services or applications that are meant for internal use only. Because healthcare organizations must be connected to the Internet to enable many information exchange functions, their data may potentially be available to every Internet-connected device in the world. "Firewalls" are used to ensure that only legitimate transactions and interactions with the external world are exposed to the internal hospital network. These hardware or software tools, collectively known as a firewall, prevent the creation of unauthorized connections from outside the organization to the internal computing systems. Firewalls can also limit the types of network traffic that are allowed to exit from the internal networked system. For example, it may restrict network traffic typically used for the sharing of files.

In order to allow legitimate external access, organizations may allow the creation of virtual private networks (VPNs). After appropriate authentication and verification, VPNs set up an encrypted path for information from an external Internet-connected computer to the organization's internal network. This allows the external computer to act as if it was physically connected to the organization's internal network and to access resources such as specialized software or shared files. This adds an additional layer of access security to the connection and ensures the communication is secure. A healthcare organization may require use of a VPN to access an EHR from outside the organization's network.

Standards for Healthcare Data Exchange

Although not always obvious, the EHR is typically an amalgamation of multiple computer systems and devices of various complexity. These systems exchange data according to common standards, languages, and processes.



Connected Systems Throughout The Institution
Operating Room
Laboratory & Radiology Departments
EHR Available Across the Institution
Gateway Device Integrating Monitors
Specialized Lab/ Radiology System
Information Transferred To EHR
PACU
ICU
FLOOR UNITS

Fig. 4.2 Information flows from connected devices across the institution into the electronic health record (*EHR*). Some departments maintain specialized software to manage the needs specific to their workflow—for example Radiology departments using Picture Archiving and Communication Systems—that are interfaced into the EHR (i.e., to allow a report to be connected to the original CT scan). Similarly networked monitor data is made available by the use of a gateway interface device. *PACU*, Postanesthesia care unit

Common connections include monitoring devices that allow automatic transfer for measured parameters into the electronic chart, infusion pumps (recording programmed settings), laboratory instruments (blood gas machines, cell counters, biochemistry analyzers, point-of-care testing devices), or systems that manage patient admission, identification, and bed occupancy (admission, discharge, and transfer [ADT] system). All of these devices and systems need methods of communicating with the EHR (Fig. 4.2). Although in some situations it may be possible to use a proprietary standard for communication between systems, it can quickly become difficult to manage across an entire institution. As a consequence, a series of commonly used standards have been established that allow the communication of healthcare information.

The Health Level-7 (HL7) standard, originally developed in the late 1980s, is still used widely in the exchange of health information. HL7 allows the transmission of data in a standardized manner among devices and clinical systems. The information can be identified to a specific patient and organized into different data types, indicating laboratory results, monitor data, and billing information. It can also cause the receiving system to perform an action, such as update previously obtained data. The HL7 standard and subsequent derivatives that address the exchange of clinical documents in a structured and identified manner support communication among different clinical systems. However, this standard was based on data exchange within different software application systems within an institution and did not envisage the proliferation of Internet-connected devices remotely accessing shared resources across many healthcare organizations.

This new paradigm led to the development of Fast Health Interoperability Resources (FHIR). This communication standard is analogous to how modern Internet applications exchange data via simple standardized requests to a central resource. FHIR enables easier integration across different types of software and integrates security features necessary due to the proliferation of mobile devices. This standard is designed to facilitate the exchange of data regardless whether it is a single vital sign or a scanned document from a physical chart.

Regulation of Electronic Data Exchange

In the United States, the 1996 passage of the Health Insurance Portability and Accountability Act (HIPAA) established a common regulatory framework that defined health information and the processes by which it should be stored and transferred, and established powers to investigate concerns regarding noncompliance with these rules.

There are four major regulatory rules: the HIPAA Privacy Rule, Security Rule, Enforcement Rule, and the Breach Notification Rule. Each update is a complex regulatory document and professional advice should be sought on the applicability and relevance of each of these to a particular situation.

The HIPAA Privacy Rule details the allowable uses and disclosures of individually identifiable health information, which is referred to as "protected health information" (PHI). Identifiers that are considered PHI are listed in Table 4.1. The privacy rule additionally defines the healthcare agencies covered by the rule. It defines processes that must be taken when working with business partners outside the healthcare agency through the creation of business associate agreements. Further, it establishes the concept of a limited data set, which is a set of identifiable healthcare information that is devoid of direct identifiers and can be shared with certain entities for research purposes, healthcare operations, and public health reasons; use of these is governed by "data use agreements."

The HIPAA Security Rule applies specifically to electronic PHI (e-PHI). The rule requires that e-PHI created, received, maintained, or transmitted by an organization should be done so confidentially and in a manner that ensures data integrity and availability. Additionally, the rule requires that threats to information security be monitored and measures be taken to mitigate these threats; this includes audits of computer systems to ensure unauthorized access has not occurred. The specification includes physical, technical, procedural, and administrative measures, all of which need to be undertaken for compliance. In general, the rule does not specify a particular set of computing resources that should be used, but instead specifies the standards to which they should be verified.

TABLE 4.1 Data Elements that Allow Patients to Be Identified

HIPAA IDENTIFIERS
Names
All geographic subdivisions smaller than a state, including street address, city, county, precinct, ZIP code
All elements of dates (except year) for dates that are directly related to an individual. Ages over 89 and all elements of dates (including year) indicative of such age
Telephone numbers
Vehicle identifiers and serial numbers, including license plate numbers
Fax numbers
Device identifiers and serial numbers
Email addresses
Web Universal Resource Locators (URLs)
Social security numbers
Internet Protocol (IP) addresses
Medical record numbers
Biometric identifiers, including finger and voice prints
Health plan beneficiary numbers
Full-face photographs and any comparable images
Account numbers
Any other unique identifying number, characteristic, or code
Certificate/license numbers

HIPAA, Health Insurance Portability and Accountability Act.
Adapted from https://www.hhs.gov/hipaa/for-professionals/privacy/special-topics/de-identification/index.html. Accessed March 3, 2019.

The HIPAA Enforcement Rule established the processes whereby a breach of the privacy rule could be investigated, and sanctions enforced. The Office of Civil Rights (OCR) within the Department of Health and Human Services (HHS) is responsible for receiving and investigating these complaints. Complaints may also be referred to the Department of Justice if it is believed that a criminal breach has occurred. Penalties for noncompliance can involve significant monetary fines or imprisonment in the context of criminal acts.

Finally, the HIPAA Breach Notification Rule defines what a breach of PHI data security is and obligates covered organizations to report to the OCR breaches of PHI that are discovered. Differing timelines for reporting apply, depending on if the breach involved greater or fewer than 500 individuals. Notification must also be provided to affected individuals and potentially to the media, depending on the number of individuals involved.

The Nature of Healthcare Information in the Anesthesia Encounter

In the conduct of anesthesia care, much of the information gathered could be considered as frequently-occurring structured data. That is, much of the information contained within the encounter can be categorized into one of a relatively small number of groups. This information is present commonly across anesthesia encounters. And the information itself can often be restricted to a small number of possible options—consider the example of an airway assessment.

This applies to information gathered in the preoperative phase of care (i.e., Mallampati classification from an airway examination) and the intraoperative phase of care (i.e., heart rate or systolic blood pressure). Furthermore, the intraoperative phase of care is marked by repetition of information at predefined intervals with measurements that may be taken in an automated manner (e.g., noninvasive blood pressure recordings every 3 minutes).

A majority of data gathered during an anesthesia case is structured, limited, and predictably repeated. However, the data are also voluminous with data generated and captured continuously on monitors, anesthesia machines, and medication pumps. More than 50 different parameters may describe a single minute of anesthesia care.

This is in contrast with the nature of the information captured in many medical specialties that are not easily constrained by content or structure. The documentation of a primary care visit may follow a standard format, however the number of variables captured may not be easily defined in advance or constrained to a standard structure; the range of possible issues to be documented may be too broad.

Anesthesia-derived data is well suited for capture into electronic charting systems. A number of mature commercially available systems are available for undertaking this task. These systems are often not standalone, and we will discuss how they are integrated in the next section.

Development and Deployment of Anesthesia Information Management Systems

Given the suitability for automated capture of recurring high-volume data, the concept of using computerized capture and storage for parts of the anesthesia record is not new. McKesson in 1934 described an early form of monitor that integrated with a vital signs data recorder (Fig. 4.3).[1] Early pioneering systems included the Duke Automatic Monitoring Equipment (DAME) System and its more compact successor, microDAME, which combined an internal monitoring platform with an integrated network architecture for central data recording.[2] Anesthesia Record Keeper Integrating Voice Recognition (ARKIVE) developed commercially in 1982 by Diatek included both a voice and touch screen interface.[3,4] Over time, other systems became available and these progressively morphed from being described as "anesthesia record keeping" (ARK) systems to "anesthesia information management systems" (AIMS) as the range of features and integration with other systems progressed.

Despite extensive development of a number of commercial systems, the use of AIMS was relatively limited in the early 2000s. Survey estimates suggest that by 2007 market penetration in academic medical centers increased from approximately 10% to approximately 75% by the end of 2014. By 2020, it is estimated that market penetration will reach 84% of all medical centers.[5-7] In the United States, the implementation of EHRs has been encouraged by federal government financial incentives including the American Reinvestment and Recovery Act of 2009, which authorized up to $11 million dollars per hospital to finance the adoption of health information technology.[8]

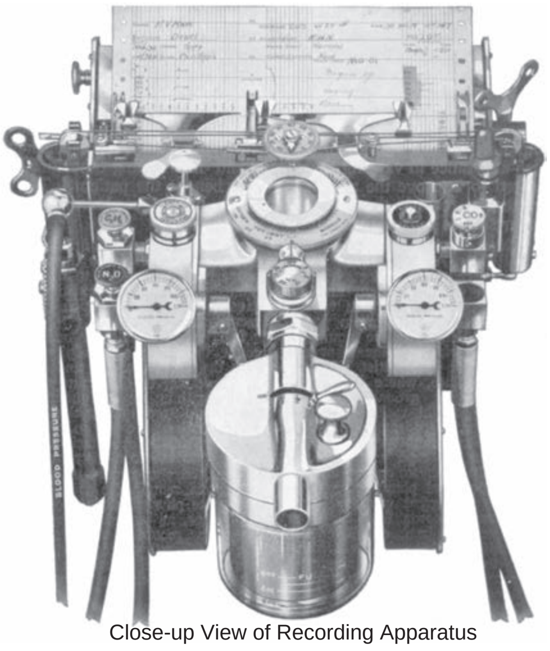


Fig. 4.3 McKesson's apparatus for the automated recording of physiologic recordings and gas mixtures. From 1934. (From McKesson El. The technique of recording the effects of gas-oxygen mixtures, pressures, rebreathing and carbon-dioxide, with a summary of the effects. *Anesth-Analg.* 1934;13[1]:1–7 ["Apparatus" Page 2])

The adoption of health information technology has resulted in the increasing integration of the anesthesia record with other clinical systems. The American Society of Anesthesiologists (ASA) has produced a statement on the documentation of anesthesia care.[9] Such systems can be used to fulfill clinical documentation needs; however, much of the promise of these systems is in the potential for integration with the broader hospital environment and secondary uses of the data that they potentially facilitate.

ANATOMY OF AN ANESTHESIA INFORMATION MANAGEMENT SYSTEM

A mature AIMS must be capable of (1) recording all aspects of the anesthesia encounter (preoperative, intraoperative, and postanesthesia care unit [PACU]); (2) must automatically gather the high-fidelity physiologic data generated by monitoring platforms and anesthesia machines; and (3) must allow the anesthesia provider to record observations regarding the conduct of the anesthetic. These three simple requirements allow us to closely specify the anatomy of an AIMS.

The first requirement for access of the same patient record during multiple phases of a case suggests the use of a system organized on a computer network, where the computer record is maintained on a central server and accessed by multiple clients. This capability requires accessibility of computer workstations at each patient-care location to facilitate documentation. The computer must be accessible during the clinical interaction but in a way that does not interfere with this interaction, which is both an issue of ergonomics and of provider behavior. In the operating room (OR), the system should be directly accessible at the time of clinical care to allow contemporaneous documentation without the anesthesia provider physically moving away from the patient or care area. In many deployments, this is achieved with a computer mounted to the anesthesia workstation alongside the monitoring equipment. Because the computer hardware is located in clinical environments, these may become contaminated with pathogens and it is important that the hardware can be cleaned in a manner that is compatible with infection control policies.[10,11]

The second requirement for automated capture of data from OR monitors and anesthesia machines is some form of interface device between the computer hardware and the hemodynamic monitors, anesthesia machines, and other patient-connected equipment (infusion pumps or ventilators)—Table 4.2. In most AIMS implementations, this interface occurs at a central level, where a network of the physiologic monitors and the central server hosting the AIMS communicate via a gateway device. Typically, interfaces use standardized data formats, such as those described earlier that transmit communication among devices and software solutions from different manufacturers and developers. Interfacing these devices with a computer network may require specialized hardware and additional cost. However, the interface enables the automated capture of

TABLE 4.2 Examples of Parameters Commonly Included in the Anesthesia Record Gathered Automatically from Different Sources

FROM CORE PHYSIOLOGIC MONITOR	
	Arterial blood pressure (systolic, diastolic, mean)
	Cardiac index
	Cardiac output
	Central venous pressure
	End tidal CO_2
	Heart rate (ECG monitoring and SpO_2)
	Intracranial pressure (ICP)
	Noninvasive blood pressure (systolic, diastolic, mean)

monitor and anesthesia machine data, freeing up clinical providers from the recording of these data elements. In light of the cost and practical challenges, some AIMS situated in low-resource settings (e.g., an office-based anesthesia location) may choose to eliminate the data interface feature.

Theoretically all electronically generated data can be recorded in the AIMS. As a consequence, the anesthesia provider must determine how much data should be incorporated into the system. Although some monitoring data is obtained with a defined frequency, such as a noninvasive blood pressure measurement taken every 3 minutes, most parameters are sampled from continuous data sources. In the OR, a pulse oximeter is not a single parameter checked at a discrete interval, but a continuous source of data. Continuous data sources (e.g., electrocardiogram [ECG], pulse oximeter, invasive blood pressure, or end-tidal carbon dioxide [$EtCO_2$] tracings) are transformed into measures that can be recorded with lower data intensity requirement, a process known as sampling. An ECG tracing may be sampled and interpreted to report heart rate and ST segment analysis results. Although it is technically possible to record continuous sources of data electronically for future review, this usually does not occur because the resulting data stream is difficult to present, archive, and review. Therefore, continuous data sources are usually reported as sampled values at a prespecified frequency.

The third requirement of an AIMS is to allow the user to annotate information (e.g., medications administered, descriptions of procedures performed, annotations to describe significant clinical events, or attestations for regulatory compliance) to the automatically collected data. Because of the similarity of one anesthesia encounter to another, some charting elements may be predefined to facilitate these documentation tasks and minimize the use of nonstructured or "free text" entries. Because of the possibility of similarity among cases, many systems use organized templates (sometimes referred to as "scripts," "templates," or "macros") that give the anesthesia provider easier access to charting elements required for a specific case type (Fig 4.4). For example, a cardiac anesthesia template may make charting elements regarding cardiopulmonary bypass prominent and easily selectable. These charting elements and templates are typically customizable at each installed site, thus providing flexibility in documenting site-specific practices or procedures.

Although the three AIMS requirements described give some specifics about how a system may be constructed, they are minimum requisites. The AIMS that only provides these requirements is not one that would be considered high value. The major advantages of AIMS come from their integration into other clinical systems and healthcare processes, which will be explored in the coming sections.

ADVANTAGES OF IMPLEMENTATION OF AN ANESTHESIA INFORMATION MANAGEMENT SYSTEM

The shift to an AIMS is a key improvement in the quality of clinical documentation. Removing the task of manual documentation of physiologic parameters has not been shown to decrease vigilance to the clinical situation and may free up anesthesia providers to perform other tasks.[12-15] An AIMS also establishes an independent, unbiased record of monitoring and machine data. Finally, legibility issues noted in handwritten charting are resolved by the use of an electronically assembled record.

Early studies compared blood pressure values recorded in handwritten charts and those recorded by automated collection. The blood pressure recordings on handwritten charts had lower maximum systolic pressures and higher minimum diastolic pressures when compared with automated collected values in OR studies.[16-18] This variation has been termed the "smoothing effect" of handwritten charting and may result in loss of clinically meaningful data.[16,19] A subsequent study demonstrated that errors in handwritten charting were clustered during high-intensity periods; that is, induction, emergence, and significant clinical events.[20,21]

Although documentation of physiologic parameters may be more complete in AIMS-charted records compared with handwritten charts other data elements may remain incomplete.[22,23] As AIMS deployments have matured, it has become apparent that documentation quality varies among providers and important clinical fields can often be left incomplete, particularly when completion requires the entry of free text.[24] Medication administration has also been incompletely documented or omitted in the AIMS compared with observed practice with a similar effect of inaccuracies occurring during high intensity periods of care.[25] AIMS support degrees of customization, including designating certain data elements as mandatory prior to completion of the case, but the decision to add more mandatory elements must be traded off against risks of arbitrary data entry ("clicking through") or provider frustration, both of which detract from the aim of improved data quality.[26] It is clear that the system design and decisions made for default values or required data elements have significant influence on the quality of record created.

One solution to the challenge of excessively burdensome documentation requirements is to use an adaptive method that changes the required elements for documentation based on the clinical context—for example, requiring documentation of bilateral breath sounds in cases involving an endotracheal tube, but not with an laryngeal mask airway.[26]

In addition, to improve compliance with the capture of individual, high-priority data elements alternative strategies may be employed. Real-time provider notification by text page for allergy or procedural notes has demonstrated increases in completeness of this documentation.[27,28] Non-real-time feedback, via dashboards, email feedback, or informational campaigns may leverage AIMS data to improve data element completion.[29] These effects may be sustained past the interventional period.[27,29]

Integration with billing processes allows the automated capture of case elements necessary to facilitate anesthesia billing, such as care start and stop times, details of the surgical procedure for which anesthesia care is being provided, the nature of anesthesia care, any separately billable procedures, and the involved providers. This information can be extracted by reporting functions and integrated with the patient identifiers. Compared to solutions that require the manual review of copies of paper records, AIMS-based workflows offer significant overall process efficiency gains; although some designs unfortunately redistribute administrative tasks to point-of-care clinicians. The potential impact of AIMS use on anesthesia procedure includes improving capture of data elements needed for billing, improved documentation to support billing of anesthesia procedures, and billing capture at time of clinical care leading to more rapid processing.[27,28,30,31]

An advantage of an AIMS system is the ability to check concurrency of anesthesia providers across one entire organization in real time. In the United States, an "in-room" anesthesia provider must be physically present when anesthesia care is provided at all times. This is typically documented by "sign in" and "sign out" documentation times. An in-room provider may be supervised by a supervising provider who may supervise a number of ORs up to maximum specified by institutional or payer policy. The AIMS system can, at time of sign-in, check that no in-room provider is documented in more than one OR simultaneously and no supervising provider exceeds the prespecified supervision ratios. Checking at time of sign-in assures that these standards are not violated by documentation errors and prevents delays in the billing process. In certain billing environments, violation of the concurrency rules may cause rejection of claims at the time of billing.

Providing an anesthesia record that can be accessed concurrently by multiple users may facilitate remote monitoring of care being provided by the in-room anesthesia provider by a supervising anesthesia provider. This increased visibility of patient care being provided at each care location allows the supervising provider to maintain a better level of awareness on the course of the case and gives the supervising provider additional guidance on management decisions. OR managers benefit from similar insight and may be able to make decisions about resource utilization based on the documented care.

Integration of Anesthesia Care Information with Operating Room Information Systems

Given the necessity of maintaining information regarding locations of care, case, patient, staffing, and case progress, it is natural to integrate anesthesia information systems with OR management systems. These systems are used in the scheduling of OR cases and assignment of staffing and supplies.

ORs are finite resources. There are a set number of available rooms, set number of available staff for these rooms, set times of availability of these staff, defined experience and specialization of these staff, and finite amount of specialist equipment for use in the rooms. As a result of these factors, ORs create enormous costs prior to any procedure being performed; efficient allocation and utilization of these resources are tied to financial outcomes of a hospital.

Each procedure performed requires allocation of procedural space, staff, and equipment that may be specific to the particular case. Therefore, it makes sense for this to be coordinated in a centralized manner. OR management systems are designed to accomplish this task controlling the allocation of these resources. These systems allow these resources to be allocated both generally (e.g., on Mondays OR 12 is dedicated for thoracic surgery cases [block scheduling]) and also specifically (e.g., John Smith is undergoing a right upper lobectomy by Dr. Jones from 11 AM to 1 PM on August 20), and further allocate staff and equipment to this procedure (case scheduling). Case scheduling may be enhanced by using historical procedural lengths to estimate future time needs stratified by proceduralist and specific procedure to be performed.

Scheduling of a case by a specific proceduralist allows the generation of a specific list of required equipment/instruments to be recalled based on anticipated requirements and proceduralist preferences. These "case pick lists" of "surgeons preference cards" can be used by supply teams to ensure that necessary equipment is available and predict future utilization.

The integration of OR management systems with AIMS provides the cases and procedures against which charting functions can be performed. Furthermore, communication between these systems can create common charting, such as phase of procedure (induction, procedure begun, procedure complete, etc.) which can be useful in understanding utilization of the OR environment for daily management and ascertaining longer-term trends. Given the enormous fixed expense incurred in the OR suite, an extensive literature has developed from the analysis of information derived from these systems regarding variability in procedure time, "turnover time" between sequentially scheduled procedures, and effect of variability of anesthesia-related case timings.[32-37]

A more recent trend is the integration of the AIMS and Operating Room Management Systems with the wider hospital-wide or "enterprise" EHR. This occurs via the development of specialized modules which account for the differences in workflow between the OR environment and the inpatient floor/ward units. These systems leverage common patient information—such as patient identification, demographics, registration, and location—then add specialization discussed above. Furthermore, this allows medical documentation, and laboratory and other diagnostic results to be made available to the perioperative providers on a single computer system.

One of the larger contrasts emerging from the OR workflow versus the rest of the inpatient environment is the process of medication documentation. When using an inpatient EHR, a provider enters a computer-based order for the routine administration of a medication. After pharmacy verification of the order, the medication is delivered to the appropriate unit for administration to the patient by a bedside nurse. In the OR environment, the medication administration decision making, selection of the medication from a pre-stocked cart, and administration is handled by an individual providing anesthesia care. This shortens the time from provider intent to patient administration. Therefore, the documentation needs to reflect the concept of care provided rather than care to be provided in the future (i.e., scheduling a medication to be administered). Given the high intensity of medication administrations, short time interval between administrations and supply from the bedside cart of the medications to be administered, the ideal documentation system should not be burdensome and allow rapid entry.

A number of features of the inpatient EHR are unavailable due to this mode of medication administration and documentation: positive identification of the patient and medication with a specified order—typically performed by "barcode" scanning of medications and patients at time of administration—is not performed as medications are typically documented retrospectively, although patients are positively identified at the beginning of each anesthesia care encounter. Additionally, automated medication interaction, dose, and allergy checking may not function in the context of perioperative administration due the practice of retrospective documentation. As the documentation of anesthesia care is quite different from that of most medical interactions. The differences in workflows must be accounted for in the development of modes of interaction and creation of documentation.

While most medications administered in the OR have a relatively short duration of action, there are important cases where medications which are administered in the OR have important consequences beyond the OR. Examples such as neuromuscular blockade, long-acting opioids, long-acting local anesthetic agents, and antibiotic administrations all may lead to important medication interactions well beyond the OR or need for modifications of postoperative care. Therefore, information regarding these administrations must be available to care providers working in the postoperative period. The use of "stand-alone" AIMS may contribute to a failure of communication of the use of these important medications. Interfaces between the stand-alone systems and enterprise EHRs allow this information to be communicated, however this poses additional development, maintenance, and deployment burden. Similarly, documentation of difficult airway management in the OR has impact beyond the OR as the patient may require emergent airway management in the intensive care unit or during future visits; information gleaned during the perioperative encounter may have enduring value to many other providers.

Development of Decision Support Tools

One of the most exciting promises of AIMS and enterprise EHRs is their ability to improve patient care by improving the decisions made by providers.[38] While medical decision making must be provided by responsible care providers, it is possible to aid decision making by providing default choices that support particular practice patterns, suggesting options which may be appropriate based on the type of care (see Fig 4.4), providing additional notification of important updated trends or results, and providing alerts based on the integration of multiple pieces of information. Based on pre-specified rules it prompts providers to consider a specific course of action or indicates additional markers of patient state. * Indicates a calculated additive MAC value of inhaled agents and propofol and dexmedetomidine infusions.

two are examples of passive decision support, the latter two are examples of active decision support. Collectively these tools are referred to as decision support and are an integral part of the perioperative information system.[39]

PASSIVE DECISION SUPPORT SYSTEMS

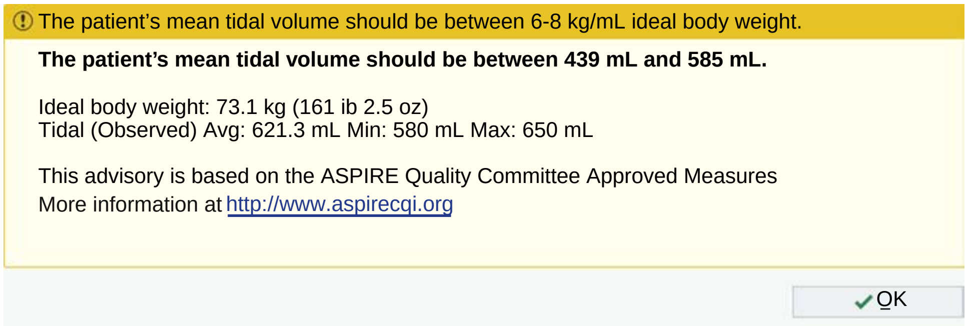
In considering these tools it is helpful to move from the simplest to the most complex. At the simplest level in the configuration of the perioperative information system, decisions regarding the choices presented to users (default doses, units, and range checks) may act as prompts for users in their selections—the so-called anchoring effect. This is an example of passive decision support. Over time it is important to continue to assess how usage aligns with users' practice to ensure that the default options presented do indeed capture the typical usage at a particular institution.[40]

Systems for the documentation of anesthetic care typically feature methods for documentation of aspects of clinical care which cluster together based on aspects of the procedure, anesthetic technique employed, or location of service. For example, a template for cases performed via a spinal anesthetic would not be configured to require documentation of the endotracheal intubation technique as these do not frequently overlap. These can form the basis of decision prompts for providers; for example, in a cardiac case, the charting element available immediately after documentation of full cardiopulmonary bypass may be regarding discontinuation of mechanical ventilation. This may act as a reminder to the provider to perform this task. The level of sophistication of these prompts depends on the time devoted to their construction at the time of system installation and configuration.

One feature to improve documentation is the utilization of mandatory documentation elements that are required prior to the completion of case documentation. Extreme care needs should dictate what elements of documentation should be made mandatory. There are likely exceptions to even the most universal documentation element and forcing completion or entry of such items may undermine trust in the entirety of the clinical documentation.

ACTIVE DECISION SUPPORT SYSTEMS

In the intraoperative space, a number of more sophisticated approaches to decision support have been developed (Fig 4.5). These decision support tools continuously evaluate the medical record for incoming information and provide feedback to the user. These tools may be separate from the EHR but access the information being recorded by that software. These tools apply rules to alert providers to aspects of care which may have been overlooked or need to be addressed. This may guide users to re-evaluate patient status (if a blood pressure monitoring gap is detected), or consider additional interventions (prompts to treat extremely elevated blood glucose) or alternative management strategies (e.g., if large tidal volumes are being used).[41-46]



The patient’s mean tidal volume should be between 6-8 kg/mL ideal body weight.

The patient’s mean tidal volume should be between 439 mL and 585 mL.

Ideal body weight: 73.1 kg (161 ib 2.5 oz)
Tidal (Observed) Avg: 621.3 mL Min: 580 mL Max: 650 mL

This advisory is based on the ASPIRE Quality Committee Approved Measures
More information at http://www.aspirecqi.org

Fig. 4.6 An example of active decision support. Providers prompted to consider the tidal volume, with information which may allow them to consider change in clinical practice. This alert is triggered in the context of an averaged measured value which is above a predefined threshold. Image: © 2018 Epic System Corporation. Used with Permission.

In order to function, these more sophisticated forms of decision support are designed around a common architecture. They run in parallel with the clinical documentation functions of the EHR. They may be built into the EHR (Fig 4.6) or may run as separate software alongside the EHR (see Fig 4.5). Regardless of the specifics of the software implementation, it is best to consider the construction of these systems as being in components.[39] In addition to the modules which capture incoming device data and enable provider manual documentation, three additional modules are added.

The first module is a component which allows a user to define a series of rules against which the incoming information will be assessed. These rules should define the population to which the rule applies (i.e., patients aged over 18 undergoing surgeries in the main hospital operating rooms), the details of the rule (i.e., determine if blood glucose value is >300 mg/dL), and then the proposed action (i.e., notify provider of this finding by text page or display a pop-up window in the EHR software). The second component is the surveillance process which repeatedly assesses the patient status against the rules using newly updated laboratory results, charting elements, monitor or device data; the process determines when a rule has been triggered. The final component is the notification module; this is the method of interacting with the user. This may be within the EHR (as a pop-up message at the front of the patient’s attention), separate to the EHR (in dedicated software running on the anesthesia workstation to display notifications regarding patient status), or alternatively may use a completely separate means of communication such as text paging, text messaging, or even phone calls.

Calibrating the alert to the clinical scenario is important and should take into account the lead time involved in data acquisition and notification. If an EHR obtains updated monitor information every minute, the rules require repeated values (to ensure non-artifact) and the output system has a 1-minute lag time, then this restricts the kinds of clinical events which are best addressed via this system. Second-to-second changes (such as in oxygen saturations) translate poorly through systems which have delays in the order minutes.[47] Therefore it is important in the design of decision support systems to target the correct events and recognize that extreme or rapidly occurring events may best be addressed via alternative notification systems or embedded into clinical monitors at the point of care.

The other key consideration is who is the intended recipient of the clinical decision support alert. In the US practice setting, there may be providers responsible for anesthesia care who are both within and outside the anesthetizing location. Alerts for providers in the OR may focus on supporting clinical decisions and selections, whereas those which are targeted at the supervising provider may be best focused on ensuring that the provider retains awareness of the current state of the OR cases being supervised. A provider in the role of OR anesthesia supervisor or manager may have additional concerns regarding allocation of anesthesia resources to support the anesthesia care being provided; notifications of significant deviations from schedules or occurrence of emergency events may be relevant to this group.

Various tools are available which incorporate these features. As discussed earlier, many passive decision support features are built into the EHR software natively. While more active decision support systems may be integrated into the EHR software it is also possible that this may come as part of stand-alone software which provides a mechanism for delivering these alerts to providers. More sophisticated implementations may additionally attempt to provide information about overall patient state drawing widely from EHR-derived data elements. This may be of use to providers in supervisory or OR manager roles seeking snapshots of the course of care.

IMPACT OF DECISION SUPPORT IN ANESTHESIA CARE

Evaluation of implementation of clinical decision support in anesthesia care has typically been focused around specific aspects of care, usually process measures. Examples include changes in ventilation parameters, perioperative β blockade, antibiotic administration, blood pressure management, administration of postoperative nausea and vomiting (PONV) prophylaxis and decreases in anesthesia agent usage (by reductions in fresh gas flow).[44,48-58] What is less well established is the relationship between clinical decision support and relevant patient outcomes. Perioperative decision support tools in the domain of perioperative glucose management in diabetic patients has been able to demonstrate differences in surgical site infection alongside improvements in perioperative glucose control in a single-center study.[59] It is likely that measurable changes in patient outcome do not come from use of a single decision rule in most circumstances. Therefore, patient outcome impact is more likely in systems which include multiple elements in their decision support; this type of implementation is not widely implemented or studied. This is supported by a single-institution study which has demonstrated that deployment of a multiparameter perioperative decision support system may reduce hospital charges and therefore resources.[45]

Integration with the Enterprise Electronic Health Record

Given the substantial shared pool of information from which the AIMS and the enterprise EHR may draw on and contribute to, it is not surprising that these systems have become integrated at many institutions into a single system. It is important to note that this increases the complexity of the EHR. For organizations where the IT support for an OR or anesthesia information system was supported and maintained through an anesthesia or surgery department relationship, the migration to an enterprise EHR will result in these duties being transferred to the hospital or enterprise-wide support group. This may reduce the customizability of these systems as changes and alterations now become handled by groups with broader responsibilities and competing priorities.

An emerging feature of EHRs, which fulfills an early promise of their utility, is meaningful transmission of data from different EHR platforms across institutions. Typically, each institution maintains an EHR that is unique to that institution. As smaller medical practices have aggregated into larger health systems, providers come under the same umbrella EHR system. This has allowed records from more health interactions to be available in a single location; a satellite clinic in a physically separate location may use a health–systemwide common EHR for documentation, making it available to the anesthesiologist who sees the patient presenting for surgery at main campus. However, when a patient presents to a nonaffiliated practice or hospital, documentation from the other institutions are unavailable and have to be obtained as printed paper, or communicated by the patient manually.

To address this issue, healthcare information exchanges (HIE) have been developed. These exchanges facilitate the transfer of health information between multiple distinct healthcare system's EHRs. This can occur in a directed way: a user at one facility chooses to send imaging data to another and uses the EHR's HIE user interface to discover records available via the HIE. These come in multiple forms but are typically based on a geographic (i.e., at the state or regional level) or a shared EHR platform (i.e., EPIC Systems Care Everywhere functionality).

In order to function, HIEs must be able to correctly match the same patient across different hospitals or clinics. Failures of this process (both incorrectly matching two patients across institutions or failing to match the correct patient across institutions) could have potential for catastrophic consequences in clinical care. Matching must consider different identifiers used at each hospital; a medical record or registration number is usually unique to the institution so is not suitable for this task. Additionally, unique identification assigned for other reasons—such as social security numbers—may not be suitable for this task as their use may shift over time and the accuracy may not match the level of confidence required for medical care. Furthermore, social security numbers may pose risk to patient privacy as they are connected to multiple other datasets including financial records.

Typically, combinations of identifiers are used to uniquely identify patients. This is joined with logic that balances a degree of uncertainty to account for the challenges previously noted with the risks of failure to match and false matches. However, this may still lead to the exchange of patient identifiers. Cryptographic solutions may be employed to prevent the need to exchange patient identifiers.

In some situations, even acknowledging the existence of a record may be revealing and pose risk to patient privacy—for example a record existing in a clinic specializing in the treatment of a particular illness may cause an inference to be drawn about a particular diagnosis. One way to minimize this issue is to limit the links to another health system's records to patients in common at the source health system. Rather than allowing a user at one institution to search freely for patients at another institution, such an approach would allow users to access the "matched" patient records at another institution only. Access to remote systems could further be controlled to limit it to the context of an active patient-provider encounter. Each of these options contains trade-offs with maximizing information availability with patient privacy.

Billing System Interactions

Billing for hospital services involves capturing accurately the resources used in the delivery of care; for example, in the perioperative setting, OR and PACU times, or specific surgical supplies and equipment used. This is recorded via the OR management system and may be linked to a broader process which manages surgical supplies, resource utilization, and scheduling. In this manner, information captured as part of OR clinical care documentation may be reused for billing, supply, and utilization management. The management of information in a centralized EHR accessible by multiple users enables simultaneous use for clinical, operational, and administrative reasons. Automated export of documented parameters may form the basis of these other uses.

In the United States, professional charges for anesthesia care are based on the duration of the care provided and the procedure for which the care is provided. Additional charges may be possible for specialized monitoring, specialized vascular access, or pain management procedures provided for postoperative analgesia. Data necessary to aid the billing process can be extracted from the EHR: for example, basic case information such as duration of anesthesia care, ASA physical status classification, staff providing for anesthesia care, and procedure performed. Reports can be run at or near to the conclusion of the anesthesia care and allow a case to be rapidly turned over to the billing staff for further processing. This may speed up the billing process and make it less dependent on paper billing sheets or other means. The implementation of automated billing alerts via text paging and email have been shown to increase prevention of documentation practices that may have been erroneous and alter reimbursement, reduce time to documentation being complete and ready to be billed, reduce time to correct errors, and increase capture of arterial line placement leading to increased reimbursement.[28,30,60]

Challenges in Anesthesia Information Management System Implementation

Just as the OR must be available for emergencies at all times, the underlying perioperative information systems which capture this activity must also be highly reliable. Despite architecting extensive EHR redundancy, backup processes must be available in cases where the system is unavailable due to hardware and software failures, or in times of planned maintenance. Typically, these result in reverting to a paper-based system for the limited periods of planned or unplanned downtime. Processes must be in place to determine how documentation captured during these downtimes is subsequently handled.

Due to the complexity of these systems it is possible that certain elements fail without the entire system becoming unavailable. For example, if the link between the monitoring platform and the AIMS system becomes unavailable, anesthesia providers may have to respond by manually entering monitoring data. Importantly, this data link failure has to be recognized. Unfortunately, it is unlikely that manual data entry will replicate the degree of completeness of the automatically gathered information. Concerns have been raised of the possibility of legal liability arising from such scenarios.[61]

In all situations where electronic records are created, a plan needs to be created to ensure that access in the future is preserved. Medical records retention requirements vary significantly by state. These typically extend for a period of time past the last contact with the health service, even up to 10 years beyond that period for adult patients. For minor patients, this period typically extends beyond the time in which the patient reaches the age of majority, even up until the patient turns 30 years old. These time periods may extend past the life expectancy of the software which created the records. Operators of EHRs, including those in the perioperative period, need to have a plan in place to ensure that data can be archived, retained, and remain accessible in line with these legal requirements.

Even with the most comprehensive of EHRs there may be a need for a physical medical record to be created as part of care—consent forms may be provided on paper, patients may write letters to their providers, and outside hospitals may send printed or paper records with a transferring patient. Decisions need to be made as to how these physical documents are retained and archived. This may involve making electronic copies which become available within the electronic record.

In situations in which separate systems are used in the perioperative process from the rest of the institution there may be situations where a paper record is printed and placed inside a patient's physical chart. When a paper record and an electronic record exist simultaneously at a given institution, then a decision needs to be made as to which has primacy. If a provider creates a paper record at the end of anesthesia care and then subsequently updates a documentation element at a later time, a process needs to be in place to ensure that this can be transferred to the patient's physical record for the paper record to maintain primacy.

Additionally, if differing systems are used in the perioperative period there may be failure of communication of important information to the entire healthcare team. While specific examples regarding medications with prolonged duration of action and challenges in airway management have been discussed above, the siloing of information in a separate system (potentially with different access requirements) contributes to the appearance of the perioperative period as being one which is completely distinct from the rest of the clinical encounter. This can contribute to failures of communication of events which occur during this important phase of care and thus potentially patient harm.

Ensuring coverage of all locations where an anesthetic may be performed can be challenging. There may be many sites where anesthesia care is provided infrequently. These are likely "non-operating room sites." In such cases the economic justification for the capital investment required to allow these sites to participate in electronic charting may not be justified. In such situations, cases performed in non-connected locations may require traditional paper charting. This creates a significant overhead as business processes need to be maintained to support the documentation of activity in these locations and ensure that the paper documentation is archived as the record of care, available for billing processes and quality assurance review.

Additional Uses for Collected Data

Secondary use of EHR data has become commonplace and is part of the value proposition of the transition to these systems. In addition to the primary purposes of clinical documentation, operational and support tasks, information contained within the EHR may find secondary uses including in the ascertainment of practice quality measures and research endeavors.

USE FOR MEDICAL RESEARCH

The rapid emergence of AIMS led to a proliferation of research into anesthesia care practices and outcomes. This proliferation has occurred because of the improved ease with which study data may be acquired. Queries of the underlying EHR databases are far quicker to perform and may be more extensive in scope than review of paper documentation in the same population. Collectively, this has led to a rapid development of retrospective database research within anesthesiology. This work has allowed quantification and identification of risk factors for both rare events, such as difficult mask ventilation combined with difficult intubation or epidural hematoma after neuraxial anesthesia, and more common perioperative events, such as acute kidney injury.[62-67]

The use of an EHR as a data source for research initiatives has offered advantages of scale in study size but also allows a wide range of risk factors to be considered. It is now routine for observational research studies using EHR data to include thousands of patient records. Given the relatively infrequent occurrence of catastrophic complications or major adverse outcomes in modern anesthetic practice, extremely large sample sizes are necessary for quantification of risk factors and rates of occurrence of significant patient outcomes.

Despite the rarity of intraoperative complications, long-term complications of the surgical procedure remain common. The ability to utilize information drawn from the entire hospital record to characterize patient outcome is extremely important to the perioperative outcome researcher, as postoperative complications may have substantial impact on patient outcome.

It has become apparent that even the largest of single center studies may not be able to generalize well across sites. Substantial heterogeneity in clinical practice exists between institutions and across geographical regions. This has driven the development of multicenter studies, facilitated by the interchange of electronic data. The Multicenter Perioperative Outcomes Group (MPOG)[*] is one example of such an undertaking, bringing together investigators from over 50 institutions across the United States and Europe who have assembled, standardized, and identified over 10 million perioperative records for research and quality improvement.[†] By including data from many sites and seeking to include diverse practice locations, such efforts aim to develop generalizable knowledge.

One of the challenges in performing this work is the level of abstraction required to summarize the patient's clinical encounter into a small number of variables for inclusion in any analysis. For example, studies on the relationship of intraoperative hypotension and postoperative outcome need to consider how to develop a measure of hypotension which summarizes multiple hours of highly granular blood pressure information into a small number of variables for inclusion in the research study. A single 3-hour case may have 60 or more non-invasive blood pressure values recorded. To include in any analysis, these need to be summarized in a manner which remains biologically plausible. Many options are available, such as averages of all collected blood pressures or time or fraction of the case above (or below) absolute (i.e., mean arterial pressure [MAP] <65 mm Hg) or relative (<20% drop from baseline MAP) thresholds. Each approach would have very different output values and may alter the results and interpretation of a research finding. With any automatically collected information, methods for handling artifacts should be considered as artifactual values may have been propagated from the monitoring platform to the automated record without clinician intervention. Given the abundance of possible data to be included in any study, it is key that a clear hypothesis and approach be developed a-priori rather than post-hoc decisions that may evaluate particular statistically or clinically significant outcomes.

While most of the research thus far has been in the context of retrospective observational studies, an emerging theme in EHR-derived research is the use of this data in near real time (within days) for prospective interventional trials. These studies attempt to gather much of the information required for the trial as a byproduct of the clinical documentation created in the EHR. Additional information regarding patient progress in the study can be appended via traditional study management software. More novel methodologies such as embedded pragmatic clinical trials where hospitals or clinics choose to standardize their management in a coordinated manner for all patients (i.e., one class of antihypertensive or another as the usual first agent for adult patients without chronic kidney disease) are dependent on EHR data collection for patient follow up and perhaps even delivering the "usual choice" via decision support tools (see Chapter 89).[68]

MEASUREMENT OF QUALITY OF CARE

Information regarding the quality of care delivered and patient outcomes may be obtained from review of the EHR. Traditional models of quality management frequently depended on the use of trained abstractors reviewing medical records and applying standardized definitions. While these systems work well, they do not scale well into high volume clinical settings due to the time-consuming nature of detailed review and the resultant staffing costs. Interest has developed in the use of EHR data for the automated derivation of quality of care information. With careful design, both process of care (i.e., appropriate antibiotic prophylaxis administration) and outcome measures (i.e., surgical site infection) may be tracked using data derived from the EHR. Decision support tools may be used to aid in the alignment of the quality measures and the clinical practice which they seek to measure. Care needs to be taken to ensure the pattern of care which may be promoted is consistent with good clinical practice.

Using automatically derived measures, it is possible to provide feedback to medical providers near the time of clinical care. Automated data extraction and processing is well developed, with feedback being described across provider groups using email, provider and institutional specific "dashboard' reporting tools, and real-time paging alerts (Fig. 4.7).[38,49,51] Various groups have worked to make available tools to enable the widespread deployment of quality measures via submission of data from individual sites to a centralized database.[69] This approach is designed to limit the need for each site to develop the required technical architecture to build and deploy such tools—a significant hurdle for many organizations. However, this likely comes at the expense of flexibility of measurement offered at each site and some degree of delay in processing.

Hello

Below is your new MPOG Quality performance report. For a case-by-case breakdown of each measure's result, click on the graph's label and you will be taken to our reporting website (login required).

If you have any questions, please read our FAQ or send them to anes-aspire@med.umich.edu. Thank you for your participation in MPOG Quality.

Sincerely,
The MPOG Team

Your Performance vs All Other Attendings
8/1/2018 to 8/31/2018
NMB-01: Train of Four Taken
You, 89% (17 / 19)
All Other Attendings, 96% (2215 / 2305)
NMB-02: Reversal Administered
You, 100% (19 / 19)
All Other Attendings, 99% (2274 / 2298)
PUL-01: Tidal Volume Under 10 mL/kg
You, 100% (16 / 16)
All Other Attendings, 98% (2589 / 2637)
BP-01: Low MAP Prevention
You, 100% (46 / 46)
All Other Attendings, 99% (6816 / 6852)
BP-02: Avoiding Monitoring Gaps
You, 98% (44 / 45)
All Other Attendings, 96% (8562 / 8955)
MED-01: Avoiding Medication Overdose
You, 100% (28 / 28)
All Other Attendings, 100% (6204 / 6213)
CARD-02: Avoiding Myocardial Infarction (Trop. ≤ 0.6)
You, 100% (16 / 16)
All Other Attendings, 100% (2880 / 2886)
TEMP-01: Thermoregulation Vigilance - Active Warming
You, 100% (18 / 18)
All Other Attendings, 93% (3151 / 3391)

Fig. 4.7 Example of feedback email summarizing performance based on an automated assessment of compliance against predefined measurement instruments using data derived from the electronic health record. This figure has been lightly edited to remove identifying information of the recipient.

Interactions of Electronic Devices with the Delivery of Anesthesia Care

Safe anesthesia care requires the maintenance of a high degree of vigilance to multiple sources of information concurrently. When combined with required clinical tasks, estimates suggest that anesthesia care has high workload requirements.[70] Workload includes the factors related to the nature of the task, the situation in which it is performed, and the operator performing it.[71] In relation to phases of OR care, workload is clearly not uniformly distributed, clustering particularly in the induction and emergence phases of care.[70] The ability of providers to engage in tasks additional to patient care is debated.

Distractions from current patient care may include communication with other team members in the OR unrelated to patient care, preparation for subsequent patients, clinical reference lookup, pursuit of educational activities, and attention to personal issues. Attempts to quantify providers' attentiveness to the clinical situation or impact of a distracting event have been performed and note that distractions are a common feature of anesthesia care.[70,72-75] Given the common occurrence and diverse sources of possible distracting events during anesthesia care, mitigating the effects of distraction to maintain focus on patient care may be a required skill of an anesthesia provider.[74]

In particular, the proliferation of electronic devices in the OR including personally owned devices by providers (such as smartphone and tablet devices) and those that are part of the anesthesia workstation (frequently Internet-connected computers for accessing EHR and documentation purposes) has raised concern for the new sources of distraction in the OR.[76] A study from eight anesthesia workstations in one institution found that the computer attached to the anesthesia workstation was used for non-anesthesia documentation purposes for 16% of the procedure time. Importantly, this study did not differentiate between time spent in this category that was related to patient care (i.e., accessing a separate lab or EHR system) or not.[77] Additional research has observed self-initiated distractions occurred in 54% of anesthesia cases.[78] Distractions related to personal matters were found in 49% of cases and related to educational activities in 24% of cases.[78]

Professional societies have issued guidelines on the role of distractions, including electronic devices, in the OR, some of which recommend the development of local policies to cover usage of electronic devices.[79-81] These policies may differentiate between clinical, educational, and personal usage of electronic devices and resources, and the appropriateness of each during patient care. It should be noted that many aspects of use of perioperative information technology, including use of personal devices, are subject to logging or recording. This may allow medicolegal review of activity performed on electronic devices contemporaneous to anesthesia care being provided in the future.

Conclusion

Information technology is very much part of the perioperative care process. It has significantly impacted clinical care, organizational performance, provider satisfaction, research, and assessment of quality of care. It is important that anesthesiologists understand the principles behind its use and be keenly aware of the benefits and potential shortcomings that applications of these tools may have. It seems likely that the future will hold a more connected perioperative environment with even more information available. The challenge, and the promise, of perioperative informatics still lies in ensuring the right people have access to the right information at the right time to enable them to make the right decision for the patient care they are providing.

Acknowledgment

The editors and publisher would like to thank Dr. C. William Hanson for contributing a chapter on this topic in the prior edition of this work.

Quality Improvement in Anesthesia Practice and Patient Safety

ANNA MARY VARUGHESE, DAVID WINTHROP BUCK, MEGHAN BROOKS LANE-FALL, and EUGENIE S. HEITMILLER

KEY POINTS

- Quality needs to be an integral characteristic of the system in which care is delivered. Improving the quality of care often requires reorganization of the way we work. A challenge to the anesthesia team is to combine efficiency in perioperative care (especially the operating room) with safety and the best quality possible.
- The growing demand from patients, clinicians, insurers, regulators, accreditors, and purchasers for improved quality and safety in health care requires that anesthesiologists and members of the anesthesia team persistently evaluate the quality of care they provide.
- Improving quality of care requires measuring performance. Clinicians have an enhanced ability to obtain feedback regarding performance in their daily work, in part because of the increasing use of information systems. Unfortunately, consensus has not been reached on how to measure quality of care.
- The goal of measurement is to learn and improve. The measurement system must fit into an improvement system; clinicians must have the will to work cooperatively to improve, and they must have ideas or hypotheses about changes to the current system of care. Also, the clinical team must have a model for testing changes and implementing those that result in improvements.
- Outcome measures, including in-hospital mortality rates, have been the basis for evaluating performance and quality. However, hospital mortality alone provides an incomplete picture of quality, does not include all domains of quality, and does not measure the overall success of the full cycle of care for a specific medical condition. A balanced set of structures (how care is organized), processes (what we do), and outcome measures (results of care in terms of patient's health over time) is needed to evaluate the quality of care overall.
- Efforts to improve quality of care require development of valid, reliable, and practical measures of quality. Identification of clinical care that truly achieves excellence would be helpful not only to the administration of anesthesia, but also to health care overall.
- Developing a quality measure requires several steps: prioritizing the clinical area to evaluate; selecting the type of measure; writing definitions and designing specifications; developing data collection tools; pilot-testing data collection tools and evaluating the validity, reliability, and feasibility of measures; developing scoring and analytic specifications; and collecting baseline data.
- The best opportunities to improve quality of care and patient outcomes will most likely come not only from discovering new therapies, but also from discovering how to better deliver therapies that are already known to be effective.
- Safety is an integral part of quality that is focused on the prevention of error and patient harm. The airline industry is often lauded as an exemplar of safety because it has embraced important safety principles, including the standardization of routine tasks, the reduction of unnecessary complexity, and the creation of redundancies. Anesthesia care teams have also adopted these principles, although many opportunities remain to further bolster patient safety.
- Healthcare providers can organize their quality improvement and patient safety efforts around three key areas: (1) translating evidence into practice, (2) identifying and mitigating hazards, and (3) improving culture and communication. Although each of these areas requires different tools, they all help health care organizations evaluate progress in patient safety and quality.

The need for improving quality and reducing the cost of health care has been highlighted repeatedly in the scientific literature and lay press. Improving care, minimizing variation, and reducing costs have increasingly become national priorities in many countries. Quality improvement (QI) programs that address these issues not only improve delivery of care but also have a positive effect on practitioner job satisfaction and organizational commitment.[1]

The goal of this chapter is to present a practical framework for developing and implementing QI programs in anesthesiology and critical care medicine that are both scientifically sound and feasible. To accomplish this goal, we review the science and approaches to QI, present measures that help evaluate whether QI programs have resulted in improvements, and describe examples of successful QI efforts.

What Is Quality?

DEFINITION OF QUALITY

W. Edwards Deming, scholar, professor, author, lecturer, and consultant to business leaders, corporations, and governments defined quality as "a predictable degree of uniformity and dependability with a quality standard suited to the customer."[1] This early definition of quality, in the context of QI, stems from its application to industrial production. However, when the term *quality* is applied to health care, the subtleties and implications of treating a human being are of prime importance, as opposed to the concerns involved in producing consumer goods. Use of the term *quality* in the context of health care can sometimes lead to defensive attitudes, economic concerns, and even ethical debates.

In the healthcare sector, quality can have various meanings to different people. For example, a daughter may evaluate quality by the level of dignity and respect with which her elderly mother is treated by a nurse. A cardiac surgeon may see quality as a percentage of improvement in the function of a heart on which he or she has just operated. A business may judge quality by the timeliness and cost effectiveness of the care delivered to its employees and its effect on the bottom line. Finally, society may evaluate quality by the ability to deliver care to those who need it, regardless of their cultural or socioeconomic backgrounds.

Despite the numerous definitions of quality in both business and medicine, a unified definition of quality in the context of QI should exist in health care. This definition of quality may have implications for both its measurement and its improvement. In order to help standardize the definition of quality in health care, the Institute of Medicine (IOM) published its own definition in a 1990 report titled *Medicare: A Strategy for Quality Assurance.* The IOM, which has since been renamed the National Academy of Medicine (NAM), defined *quality* as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[2] Inherent in this definition are the elements of measurement, goal orientation, process and outcomes, individual and society preferences, and a dynamic state of professional knowledge. This definition of quality in health care has gained widespread acceptance. A similar definition is offered by the U.S. Government Department of Health and Human Services, which defines quality in public health as "the degree to which policies, programs, services, and research for the population increase desired health outcomes and conditions in which the population can be healthy."

AIMS OF QUALITY IN HEALTH CARE

In the 2001 report, *Crossing the Quality Chasm,* six aims for quality in health care were outlined.[3] These aims of safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity included and extended the issues of patient safety described in their earlier report *To Err Is Human.*[4] The aims have been adopted by many organizations, including the Institute for Healthcare Improvement (IHI), a United States nongovernmental agency devoted to advancing QI and patient safety in health care. These aims serve as a basis on which quality is evaluated and improved and are described as follows.

1. Safety. No patient or healthcare worker should be harmed by the healthcare system at any time, including during transitions of care and "off hours," such as nights or weekends. Errors may be categorized as either failure of an action to occur as planned, such as the administration of a wrong medication to a patient, or having the wrong plan altogether, such as misdiagnosing and subsequently mistreating a patient.[4] As much as possible, patients should be informed about the risks and benefits of medical care in advance. If a complication does occur, medical staff should make full disclosure, provide assistance to the patient and family, and exercise due diligence in preventing any recurrences of the error.
2. Effectiveness. Effective medicine requires evidence-based decisions about treatment for individual patients, when such evidence exists. The best available evidence should be combined with clinical expertise and patient values in forming a treatment plan. With effective care, medical practitioners avoid underuse by providing a treatment to all who will benefit and avoid overuse by refraining from giving treatment to those unlikely to benefit.
3. Patient-centeredness. Patient-centered care is respectful of individual patient preferences, needs, and values and uses these factors to guide clinical decisions.[4] More specifically, according to Gerteis and colleagues,[6] patient-centered care encompasses respect for patients' values; coordination and integration of care; information, communication, and education; physical comfort; emotional support that relieves fear and anxiety; and involvement of family and friends. The dramatic increase in access to health information on the Internet has resulted in more patients who are well informed and proactive in their care. Patient-centered care embraces this trend and shifts more of the power and control to patients and their families. Examples of patient-centered care include shared decision making, patient and family participation in rounds, patient ownership of medical records, schedules that minimize patient inconvenience, and unrestricted visitation hours.[7]
4. Timeliness. Reduced wait time is important to both patients and healthcare practitioners. Long waits signal a lack of respect for a patient's time. Furthermore, delays may not only affect patient satisfaction, but may impair timely diagnosis and treatment. For healthcare workers, delays in availability of equipment or information may decrease job satisfaction and the ability to perform their jobs adequately.
5. Efficiency. Rising costs have increased scrutiny of waste in health care; this includes waste in labor, capital, equipment, supplies, ideas, and energy.[8] Improved efficiency reduces waste and results in an increased output for a given cost. Examples of efficiency measures include mean length of hospital stay, readmission rate, and mean cost of treatment for a diagnosis. The elimination of waste can result in better quality of care for patients at the same or lower cost.
6. Equity. Equitable care does not vary in quality based on personnel. The NAM defines equitable care at two levels. At the population level, equitable care means

reducing or eliminating disparities between subgroups. At the individual level, it means absence of discrimination based on factors such as age, gender, race, ethnicity, nationality, religion, educational attainment, sexual orientation, disability, or geographic location.[3]

Another framing of quality is the "quadruple aim" proposed by Bodenheimer and Sinsky[5] and adopted by the IHI. These four aims include better care, better outcomes, lower cost, and better work life for the healthcare workforce. This last aim was added to the IHI's previous "Triple Aim" in recognition that increasing clinician burnout represents a threat to high-quality care.[5]

DEMING'S SYSTEM OF PROFOUND KNOWLEDGE

Before learning about frameworks and tools for improvement, it helps to have an understanding of the theory behind improvement work. W. Edwards Deming wrote about two different types of knowledge: subject matter knowledge and profound knowledge. Subject matter knowledge is professional expertise, such as expertise in anesthesiology. Profound knowledge is the knowledge of improvement. The most significant improvement occurs where these two types of knowledge overlap. Deming divides profound knowledge into four different categories: appreciation of a system, the theory of knowledge, understanding variation, and psychology.

The first area of profound knowledge is appreciation of a system. A system is a network of interdependent components working together for a common aim.[6] It is often said that "Every system is perfectly designed to get the results it gets." If a system is underperforming, it is because it has unintentionally been designed to underperform. If this is the case, it is our responsibility to manage the system to get the results we want.

The second part of Deming's profound knowledge is the idea that knowledge requires a theory. Information by itself is not knowledge. For example, a dictionary contains information, but it is not knowledge. We must have a theory behind our improvement work, not just data, if we are going to learn.[6]

In order to learn, we must additionally understand variation and how to react to it. Deming says that "life is variation."[6] Common cause variation is variation that is inherent to the process. Special cause variation is variation from causes that are not inherent to the process but arise from specific circumstances. A process which only has common cause variation is in statistical "control." On the other hand, a process that has both common cause and special cause variation is an unstable process.[7] Two common errors in improvement work are acting upon common cause variation as if it were special cause, and acting upon special cause variation as if it were common cause.

The last area of profound knowledge is psychology. This is often the most challenging part of improvement work. Deming believed in intrinsic motivation, and the need to nurture people's joy in work and intrinsic motivation to learn.[6] More recently John P. Kotter describes eight steps to change in his book *The Heart of Change*. These are increase urgency, build the guiding team, get the vision right, communicate for buy-in, empower action, create short-term wins, don't let up, and make change stick.[8]

Approaches to Quality Assessment

QUALITY ASSURANCE VERSUS CONTINUOUS QUALITY IMPROVEMENT

Although the terms *continuous quality improvement (CQI)* and *quality assurance (QA)* were used interchangeably in the past, substantial differences existed between the two. Most medical CQI systems were built on the foundation of a traditional QA system that used *standards* to define quality.[9] Standards can be defined as an "acceptable" level of performance. For example, a standard for overall mortality after cardiac surgery is less than 3%; however, is 3% (vs. 4% or 2%) mortality after cardiac surgery acceptable? Similarly, a standard for head injury evaluation is a computerized tomography (CT) brain scan within 4 hours of admission, but in certain circumstances, patients with head injury may warrant a CT scan sooner than that.

Most standards are inherently arbitrary and often lack consensus among medical professionals.[9] Additionally, QA systems typically react only when a standard is not met. Examples of traditional standard-based QA systems were peer review systems and morbidity and mortality reviews. These systems often exist to flag certain cases or practitioners for intense review. Practitioners may regard this intense review as a punishment because only "failures" or "bad apples" are identified, and process failures are not connected with the outcome on every case. Thus, QA systems are inherently judgmental and, if not carefully administered, can hold practitioners responsible for random causes over which they have no control. CQI systems, on the other hand, recognize that errors occur and require different responses. Often excellence in health care is not identified by analysis of QA systems. Excellence is sometimes defined by the lack of failure. Is there a difference between good (acceptable) and excellent health care?

Systems within health care are a series of interlinked processes, each of which results in one or more outputs. CQI systems, as opposed to QA systems, include an explicit approach to process and the use of specifications to improve a process or outcome. A specification is an explicit, measurable statement regarding an important attribute of a process or the outcome it produces.[9] Specifications identify variables that need to be measured, but typically do not set acceptable limits or standards. Once specifications have been defined in a CQI system, all outputs or cases, not just failures, are evaluated against these specifications. The system then attempts to correct errors by fixing the process rather than the people. Thus, CQI aims to change the process and prevent quality failures before they happen by building improvements into the process. To quote Philip Crosby, "The system for causing quality is prevention, not appraisal."[10]

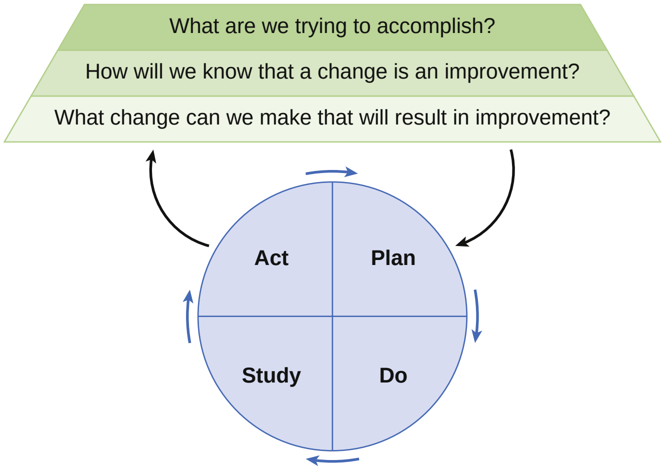
FRAMEWORKS FOR IMPROVEMENT

Model for Improvement

The journey toward improvement can be made more efficient and more effective with a systematic approach. The Model for Improvement, developed by the training and management consulting company Associates in Process Improvement (http://www.apiweb.org), is one such

TABLE 5.1 Steps of a Plan, Do, Study, Act (PDSA) Cycle

Step	Description
Plan	Make a plan for the test of change. Include predictions of results and how data will be collected.
Do	Test change on a small scale. Document data, observations, and problems that occur.
Study	Use data gathered from previous stages to build new knowledge and make predictions. Knowledge is gained from both successful and unsuccessful changes.
Act	Adopt the change, or use knowledge gained to plan or modify the next test of action.



What are we trying to accomplish?
How will we know that a change is an improvement?
What change can we make that will result in improvement?
Act
Plan
Study
Do

Fig. 5.1 Diagram of model for improvement. (From Langley GJ, Moen RD, Nolan KM, et al. *The Improvement Guide: A Practical Approach to Enhancing Organizational Performance.* San Francisco: Jossey-Bass; 2009. With permission from John Wiley & Sons.)

approach adopted by organizations across varied disciplines and is currently the approach used by IHI. It is a structured, dynamic model that applies the scientific method to testing and implementing a change.[7] In 1939, Walter A. Shewhart, a physicist, engineer, and statistician, introduced the science of modern QI.[11] He introduced a three-step scientific process of specification, production, and inspection, stating that "these three steps must go in a circle instead of in a straight line."[12] In the 1940s, his protégé, W. Edwards Deming, applied these concepts to government and industry and developed the Plan, Do, Study, Act (PDSA) cycle (Table 5.1).[13] A modification of the PDSA by the addition of three fundamental questions (as explained in the next paragraph) resulted in the Model for Improvement (Fig. 5.1).[12]

Beginning an improvement project with the three fundamental questions for improvement helps set a clear direction for the project, define what success will look like, and hypothesize successful interventions. The three fundamental questions for improvement are:

1. Aim: "What are we trying to accomplish?" The aim (or objective) for improvement should be specific, measurable, actionable, relevant, and time-specific (also referred to as a SMART aim). Ideas for improvements may come from interviewing those involved or affected by the process, such as staff or patients. Ideas may also come from examining previous data on operational, clinical, or financial processes.
2. Measure: "How will we know if change is an improvement?" Ideally, measures should be linked directly to the aim or goal of the project and should ensure that the interests of the stakeholders of the process are represented.[7] Quantitative measures should be used when possible to measure change over time. These measures provide the feedback that enables one to know whether or not the change is an improvement. However, not all projects have an easily quantifiable outcome and the outcome may be more qualitative. It is worth the time and effort to identify opportunities to translate goals into quantifiable outcomes if possible. These can be easier to use to communicate success.
3. Changes: "What changes can we make that will result in improvement?" Ideas for changes that result in improvement often start with observations, modeling the success of others, and brainstorming. The more intimate the understanding of a process and its key drivers, the higher the likelihood of generating successful changes.

The three fundamental questions are followed by a PDSA cycle, which is the framework for testing and implementing previously generated ideas for change. Improvement may require multiple cycles of preferably small tests of change over time. By testing changes on a small scale before implementation, risk is mitigated. Small tests of change may also help overcome individuals' resistance to change. Through repeated cycles, increased knowledge is acquired, and actions are continuously modified or changed. Measures defined in the first part of the model help determine whether or not a change is a success. These measures are often plotted over time on run charts or control charts (Figs. 5.2 and 5.3). Knowledge can be gained from both successful and unsuccessful tests! Finally, PDSA cycles both test a change and implement a successful change on a larger scale or in diverse clinical areas.

Lean Methodology and Six Sigma

In addition to the Model for Improvement, CQI initiatives have many other frameworks. Two of these frameworks, Lean Production and Six Sigma, are briefly discussed here. These frameworks are sometimes combined, as in "Lean Six Sigma." Regardless of which framework is employed, benefits are gained by retaining a structured and consistent approach to CQI.

Lean methodology has its roots in Japanese manufacturing, particularly in the Toyota Production System.[14] More recently, Lean has found success in the healthcare industry. Two notable examples of its use are Virginia Mason Medical Center and ThedaCare, Inc., both of which have transformed their organizations through the application of Lean principles. In fact, ThedaCare reported $3.3 million in savings in 2004 with reduced accounts receivable, redeployed staff, reduced phone triage times, reduced time spent on paperwork, and decreased medication distribution time.[14]

Lean methodology is focused on creating more value for the customer (i.e., the patient) with fewer resources. Every step in a process is evaluated to differentiate those steps that add value from those that do not. The ultimate goal is to eliminate all waste so that every step adds value

TABLE 5.2 Steps in the Lean or Six Sigma Process

Step	Description
Define	Define the goals of the improvement project. Obtain necessary support and resources and put together a project team.
Measure	Establish appropriate metrics. Measure baseline performance of the current system.
Analyze	Examine the system for possible areas of improvement.
Improve	Improve the system through implementation of ideas. Statistically validate improvements.
Control	Institutionalize the new system and monitor its stability over time.

to a process. Other key components of Lean include reducing unevenness of workflow—for instance, what we might find in intensive care unit (ICU) admissions or emergency cases—and eliminating the overburdening of people and equipment. Five principles govern Lean improvement:[7]

1. *Define the value* that the customer is seeking. Virginia Mason Medical Center has a "patient-first" focus for all its processes.[14]
2. *Identify and map* the value stream. If evaluating preoperative assessment, map the physical flow of a patient from the scheduling of a procedure through the day of surgery (history and physical, preoperative counseling, laboratory tests, imaging, consultations). In this process, all of the steps are accounted for, including the back-and-forth flow of the patient to the front desk, to the laboratory, and so on. Time spent during each step of the process should be documented.
3. *Smooth the flow* between value-added steps. Eliminate steps that do not add value to the overall process and are likely a poor use of time or effort on the part of the caregivers or the patient. An example of this process might be eliminating unnecessary tests or consultations in a patient's preoperative evaluation and reducing excess wait times that are the result of correctable inefficiencies.
4. *Create pull* between steps. Customer demand should trigger the start of a downstream process. Examples include opening operating rooms (ORs) or increasing staffing based on surgical demand, as opposed to having a fixed amount of time for each surgeon or surgical division.
5. *Pursue perfection* by continuing the process until you have achieved ultimate value with no waste.

The transformation of Motorola in the 1980s from a struggling company to a high-quality, high-profit organization helped give rise to the Six Sigma methodology. Two key fundamental objectives of Six Sigma are a virtually error-free process and a large focus on reducing variation.[15] In fact, a Six Sigma process, or a process whose frequency falls six deviations from the mean, corresponds to just 3.4 errors per million.

Health care often falls far short of this standard. In a 1998 report, Chassin[16] reported that hospitalized patients harmed by negligence were at a four sigma level (10,000/million), patients inadequately treated for depression were at a two sigma level (580,000/million), and eligible heart attack survivors who failed to receive β-adrenergic blockers were at a one sigma level (790,000/million). In contrast, Chassin found that anesthesiology was the one healthcare specialty that approached the six sigma level, with deaths caused by anesthesia as low as 5.4/million.[16] In comparison with health care, airline fatalities were a two sigma process (230/million) and a traditional company operated around four sigma, the equivalent of 6200 errors/million.[16] Considering that errors are often tied directly to cost, this error rate has significant financial implications.

Six Sigma is similar to the Model for Improvement in that it makes use of a simple framework to guide improvement, in this case using Define, Measure, Analyze, Improve, Control (DMAIC).[15] The DMAIC steps are described in Table 5.2. As mentioned earlier, many organizations have found the greatest benefit by combining elements of different methodologies in their CQI work. One popular example of this is Lean Six Sigma, which combines improvements in flow and value with reduction in error and variation. Furthermore, individual tools from these strategies, such as PDSA cycles or DMAIC processes, can be applied where appropriate.

The Value Framework in Health Care

Since quality in health care is focused on patient outcomes, another approach to quality is the value framework. Quality relative to cost determines value. Hence, in health care, value is defined as the patient health outcomes achieved per dollar spent.[17] Value should define the framework for performance improvement in health care. Value includes goals already embraced by health care such as quality, safety, patient centeredness, and cost containment; the value framework allows for a way to integrate these goals.

Because value is always defined around the customer, in the healthcare industry it is what matters most to patients, and unites the interests of all the stakeholders in the healthcare system. Thus, when value improves, not only do patients, payers, providers, and suppliers all benefit, but the economic sustainability of the healthcare system also improves. As such, value should be the overarching goal of healthcare delivery. According to Porter, the failure to adopt value as the central goal in health care and the failure to measure it, are the most serious failures of the medical community.[18]

Value measurement today is limited and highly imperfect. Value should be measured by outputs not inputs. Thus, value is dependent on patient health outcomes and not the volume of services delivered. The only way to accurately measure value is to track individual patient outcomes and costs longitudinally over the full cycle of care, which can vary from 30 to 90 days for hospital care and 1 year for chronic care.

Value is not measured by processes of care utilized by a patient. While process measurement is an important component of improvement, it should not be substituted for measurement of patient outcomes. Outcomes and cost should be measured separately. Outcomes, the numerator of the value equation, refer to the actual results of care in terms of patient health and should consist of a set of multidimensional outcomes that, when considered together, constitute patient benefit. Cost, the denominator of the value equation, should include total costs involved in the full cycle of care for the patient's medical condition. Most physicians do not know the full costs of caring for a patient, thus they lack the information to make real efficiency improvements.

Outcomes measurement is critical to driving rapid improvements in health care. Without a feedback loop that includes the outcomes achieved, providers lack the information they require to learn and improve. Effective outcome measurement is hampered by several problems. First, there is a lack of consensus as to what constitutes an outcome. Second, electronic medical record (EMR) systems often do not facilitate the capture of longitudinal outcomes measures with appropriate scope; these systems may focus too narrowly or too broadly, giving only a partial view of patient outcomes. Third, outcomes such as infection rates may vary substantially by medical condition. Finally, true outcome measurement has been limited because the cost of gathering longitudinal patient results is high, due in part to fragmented organizational structures and poor EMR interoperability.

Cost is the most pressing issue in health care. Current cost measurement approaches have not only hampered our understanding of costs but also contributed to approaches involving cost-containment. A focus on cost-containment rather than value improvement can be dangerous and is often self-defeating. Two major problems associated with cost measurement include: (a) cost aggregation, wherein we often measure and accumulate costs based on how care is organized and billed for, that is, costs for departments, discrete service areas, and line items such as supplies or drugs and (b) cost allocation where the costs of healthcare delivery are shared costs, involving shared resources and as such are normally calculated as the average cost over all patients for a department. A good example of this is the hourly charge for the OR. However, to truly understand costs, they must be aggregated around the patient, rather than discrete services, and shared costs must be allocated to individual patients on the basis of each patient's actual use of the resources involved. Finally, the perspective used to calculate costs matters and patient costs including lost work may not be included in the analysis.

Proper measurement of outcomes and costs is the single most powerful lever for improving healthcare delivery and although current measurements are highly imperfect, the process of measurement has begun. As Michael Porter outlines in the framework papers underpinning his value commentary in the *New England Journal of Medicine*,[18] if all the stakeholders in health care were to embrace value as the central goal and measure it, the resulting improvements would be enormous.

Quality Improvement Measures and Tools

The concept of using measurement to drive improvement has its origins in both medicine and industry. The use of data to improve patient health originated in the mid-1800s with two pioneers, Florence Nightingale and John Snow. Nightingale used data on mortality among British soldiers to drive improvements in sanitation in field hospitals. Similarly, Snow used data on the incidence and geographic location of cholera to make the connection between the incidence of the disease and water obtained from the Broad Street water pump. In the early 20th century, Ernest Codman, a surgeon at Massachusetts General Hospital, was the first to advocate tracking of patient outcomes so that adverse events could be identified and improvements in care made for future patients.[19] In the 1960s, Avedis Donabedian emphasized the importance of measurement and described a model for evaluating quality of health care based on structure, process, and outcomes—*structure* being the environment in which health care is provided, *process* being the method by which it is provided, and *outcomes* being the result of the care provided.[20] More recently, in 1991, Paul Baltaden and Don Berwick developed the IHI, which has become one of the leading organizations in the application of improvement science to health care.[21]

In QI, measurement can serve many purposes. It can be used to identify problems and establish baseline performance, inform and guide QI projects, select and test changes for improvement, and assess and align progress with organizational goals. Selecting and developing measures that are useful can be challenging. Optimal measures must be comprehensive, carefully defined, tailored to the target audience, and involve minimal measurement burden. Target audiences usually include clinical staff, so measures should address and align with clinical targets for specific patient populations with whom the staff work. Measures should pass the face validity test with clinical practitioners delivering care. National or organizational measures, if applicable, can also be used, but they may not always be relevant or credible to the local target audience. Within an organization, target audiences should include system leaders, so measures should also align with organizational priorities and strategic goals.

PROCESS AND OUTCOME MEASURES

Measures should include the following:

1. Process measures that address the processes of healthcare delivery (e.g., perioperative β-adrenergic blocker administration for patients, antibiotic administration for prevention of surgical site infection)
2. Outcome measures that address patient outcomes from delivery of these services, such as clinical and functional outcomes or satisfaction with health (e.g., morbidity, mortality, length of stay, quality of life)
3. Balancing measures that address the possible consequences of changes in the process (e.g., when process improvements are made to improve efficiency, other outcomes, such as patient satisfaction, should not be adversely affected)

Each of these measures has advantages and limitations.[22] A comprehensive set of measures should include at least one process, outcome, and balancing measure. In addition, structural measures, such as ICU nurse-to-physician staffing ratios, can be important to include when appropriate.[23,24]

Healthcare providers readily accept process measures because they demonstrate the degree to which caregivers can influence a process with the intention to improve patient outcomes. Practitioners generally feel more accountable for the process of care than its outcomes, because outcomes may be affected by many other variables.[22] An obstacle to using process as a measure of quality is sustainability; frequent updating is required as the science of medicine advances.

Process measures, which evaluate how care is delivered, may be easier to measure and implement than outcome measures and can provide important insight into care.[25] Process measures can provide immediate feedback regarding performance, allowing for rapid improvements in care. If an outcome occurs infrequently, providers will be unable to obtain meaningful feedback on outcomes on a timely basis. For example, evidence of improved rates of catheter-related bloodstream infections (CRBSI; an outcome measure) may require 12 to 24 months of data (because few patients develop infections), whereas improved adherence to evidence-based practices to reduce infections (process measures) may be observed within a week (because all patients can be evaluated to determine whether they received the intervention).

Process measures have two other important advantages. First, they generally have face validity for providers, meaning that providers believe they can use the data to improve care; and second, because risk adjustment is less important, broad implementation is feasible. Moreover, joint efforts among providers, professional societies, and external government or payer agencies have made process measures more feasible.[25]

To be valid, process measures should have causal links to important outcomes; a change in the process should produce a desired change in outcome. One of the best opportunities to improve patient outcomes may well come from discovering how to deliver therapies (processes) that are known to be effective in producing a desired outcome.[26] For example, hand hygiene and application of chlorhexidine to sterilize the skin site before insertion of a central venous catheter (CVC) are two of five processes known to reduce CRBSI.[27] Process measures such as these are indicators of whether patients reliably receive evidence-based interventions known to prevent complications.

Although process measurement is useful and should continue, there is no substitute for measuring outcomes, whose principal purpose is not comparing providers but enabling innovations in care. Process measurement should largely be an internal effort, but should not be the means of external measurement and reporting of quality and value. As mentioned above, measuring value requires measuring actual outcomes over time.

Outcome measurement refers to the actual results of care in terms of patient health over time; for each medical condition there is a set of multidimensional outcomes that together constitute patient benefit. These include survival, functional status, and sustainability of recovery. Outcome measures relate directly to the health status of the patient. Patient satisfaction with care is a process measure, not an outcome. Patient satisfaction with health is an outcome measure. However, current measures for outcome often focus on the immediate results of particular procedures or interventions rather than on the overall success of the full cycle of care of a medical condition.

The relative focus on outcome and process measures will depend on balancing the collection of data between that which is scientifically sound and that which is feasible. In general, a balanced set of process and outcome measures helps inform improvement efforts and provides evidence that efforts have made a difference in the lives of patients.

For measurement to be effective, the following principles are important. First, measures should focus on something that the improvement team has the power to change and should initially be simple, small-scale measures that focus on the process itself and not on people. Second, measures should be practical, seek usefulness—not perfection—and fit the work environment and cost constraints. Third, data for measurement should be easy to obtain; finding ways to capture data while the work is getting done allows measures to be built into daily work. Fourth, qualitative data (e.g., reasons for patient dissatisfaction in the patients' own words, observations to contextualize quantitative data) are highly informative and should complement quantitative data (e.g., percentage of patients satisfied with care). Finally, when using measures, balance is key; a balanced set of measures can help answer the question, "Are we improving parts of our system at the expense of others?"

Measurement should not overwhelm the change process. Improvement teams should minimize the burden of measurement whenever possible. Measurement can have both direct and indirect consequences on resource use, provider behaviors, and patients.[28] Measurement of performance and outcomes of care can be costly, especially if the data collection process is manual and involves chart reviews. The burden of measurement is reduced with an EMR system and computerized order entry, although these information technology systems are costly to implement and maintain. Additionally, these resources may not be equally available throughout a system or organization, leading to disparities in the care provided.

Measurement fixation is an unintended consequence on healthcare staff behavior that may occur with the use of process measures. For example, when a process measure such as "the percentage of diabetic patients who received an action plan" is used rather than an outcome measure such as "improved patient understanding about diabetic management," the measure is perceived by the clinician as defining what is important. Thus, measurement of the process becomes the priority, rather than the intended outcome.[28] Alternatively, the clinician may become so focused on what is being measured that different aspects of care are not equally prioritized. In addition, a predominance of process rather than outcome measures can stifle innovation by scripting a process, thus inhibiting process-level innovation. Practice variation does have some utility because medical practice is dynamic, and it is through the trial of new methods of care that innovation occurs. Finally, QI performance measures may not match patient preferences for clinical care. Performance measures that do not take patient preference into account can lead to decreased patient satisfaction, trust, and confidence in their healthcare practitioners and system.[28] Thus, selection of a set of appropriate measures with the attributes described previously can be a balancing act that includes weighing the tradeoffs involved.

Consumers, payers, and employers are increasingly requesting outcome measures to both improve care and decrease cost. Even national governmental bodies are influencing the measurement and reporting of quality in health care. In the United States, the Centers for Medicare and Medicaid Services (CMS), the single largest healthcare purchaser, requires hospitals and physicians to participate in the Quality Payment Program (QPP). This program requires providers to demonstrate quality by either participating in an Advanced Alternative Payment Model (akin to a quality collaborative or participants in a bundled payment model) or by accumulating points through the Merit-based Incentive Payment System.[29] The United Kingdom Quality and Outcomes framework[30] is an analogous system. These quality mandates have fundamentally changed the ways that clinicians, hospitals, and health systems engage in and report QI activities.

ANALYSIS AND DISPLAY OF QUALITY IMPROVEMENT DATA

Interpretation of data and understanding of process variation are fundamental to QI work. Data elements central to improvement are first and foremost—those data are collected as a basis for action. Second, interpretation of data is made within the context of the process. Last, the analysis technique should filter out noise in the process. Aggregate data or summary statistics typically do not filter out noise in the system and do not present a broad enough context to point practitioners in the direction of proper action or process improvement.

Shewhart postulated that data contain both signal and noise; to be able to learn, one must separate the signal from the noise.[31] CQI science defines two types of variation within a process: random variation and specific variation. Random variation, also known as common-cause variation, results from differences in the inputs that a process receives or inherent factors in the process itself. Random variation is the random background noise within a system and occurs in the process all the time. Specific variation, also known as special-cause or attributable variation, is not present all of the time as background noise, but rather arises from one or more specific causes that are not part of the system. A process is considered to be unstable when specific variation exists, and efforts should be made to learn about the special causes for this variation. A stable process exists when specific variation no longer occurs, leaving only random or common variation.[9] CQI aims to eliminate specific variation for every process so that only random variation remains. A standards-based QA system fails to distinguish random cause from special cause and attempts to correct all variation. Attempts to correct random variation will necessarily fail—a process CQI defines as "tampering." When a process exhibits only random variation, the process should be evaluated to determine whether it is functioning at an acceptable level. If it is not, the process will need to be changed so that the average is moving in the desired direction. Standardization of a process is often the key to reducing random variation and improving a process.

Run Charts and Control Charts

Run charts and control charts are graphic displays of data that enable observation of trends and patterns over time. They are the best tools for determining whether improvement strategies have had an effect. A run chart (see Fig. 5.2), also called a time series chart, plots the variable or measure being studied on the vertical axis and plots the time on the horizontal axis. The average, or centerline, is the median. At least 12 data points are required to establish a baseline, and at least 20 to 25 data points are required to detect trends and patterns. Run charts should be annotated with tests of change to provide the context within which data can be interpreted. Four rules can be used with run charts to determine whether nonrandom patterns exist or to detect whether the change has led to an improvement:

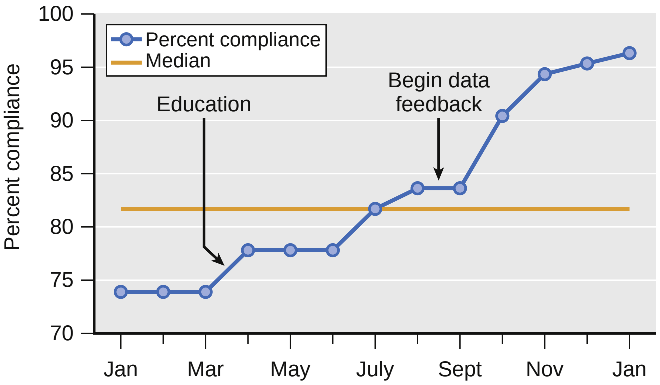


Fig. 5.2 Example of a run chart. This chart shows the plot of a performance measure over time. The horizontal (*x*) axis represents time in months, and the vertical (*y*) axis represents the performance measure—the percentage of compliance with the timing of preoperative antibiotics.

1. A shift is indicated by six or more consecutive points above or below the median.
2. A trend is indicated by five or more points all increasing or all decreasing.
3. A run is defined as a series of consecutive points on the same side of the median line.
4. An astronomical data point is an unusual point that is obviously different in value (an outlier).[7]

Because change is by nature temporal, run charts in which data are presented over time are powerful tools for interpreting data within the context of the process.

A control chart (see Fig. 5.3),[32] also known as a Shewhart chart,[7,11] is an extension of a run chart and is used to distinguish between specific and random variation. As on a run chart, the variable is plotted on the vertical axis and time on the horizontal axis. However, with a control chart the centerline or average is the mean, rather than the median, and the upper control limit (UCL) and lower control limit (LCL) are calculated. The UCL and LCL correspond to ±3 sigma from the mean. A process is considered to be "in control," or stable, when data points are within these control limits.[11] Random variation, or variation that is the result of the regular rhythm of the process, produces a stable process. However, in an unstable process that contains variation from special causes, data points exceed the UCL or LCL.[33]

Failure Modes and Effects Analysis

A failure modes and effects analysis (FMEA) is a tool to help identify problems in a process before they occur and cause harm.[7] An FMEA can help you decide where to target your improvement efforts. In addition, the proactive approach makes it especially useful before implementing a new process.

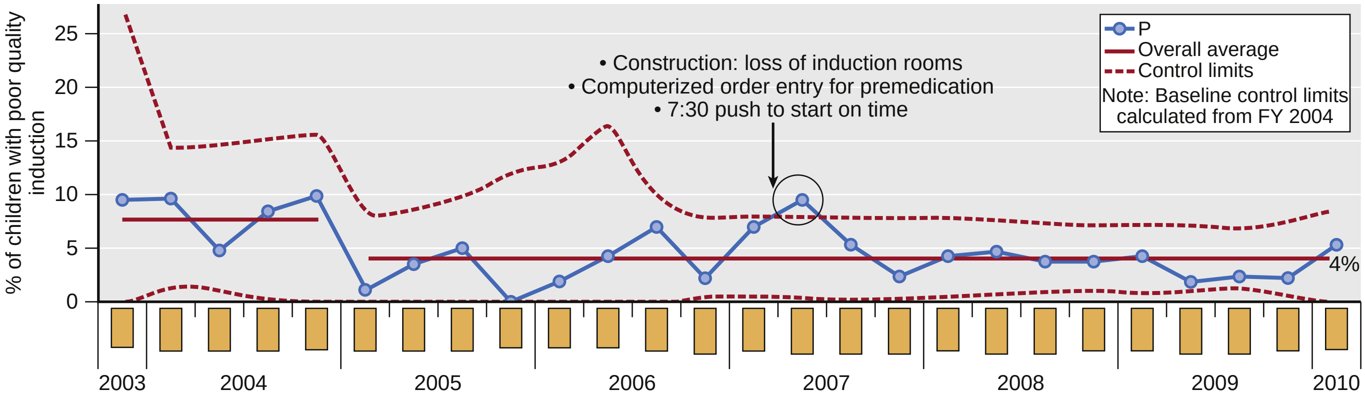

Fig. 5.3 Example of a control chart that monitors the quality of the anesthesia induction process, as measured by an induction compliance checklist. The solid red line marks the mean, and the dashed lines indicate the upper control limit and lower control limit, which are ±3 standard deviations from the mean. The circled point represents a single special cause variation in quality of induction. (From Varughese AM. Quality in pediatric anesthesia. *Paediatr Anaesth.* 2010;20:684–696.)

An FMEA reviews the steps in a process, the potential failure modes (what could go wrong), failure causes (why would the failure happen?), and failure effects (what would be the consequences?). (IHI, QI Essentials Toolkit) After listing the steps in a process, a risk profile number is calculated based on the likelihood of occurrence, likelihood of detection, and severity. Improvement efforts are then targeted at the steps with the highest risk profile number.

A simplified FMEA is a quicker version of the FMEA that can help guide improvement work. A simplified FMEA consists of listing the steps in a process, listing potential failures that could go wrong for each step, and brainstorming interventions for each of those possible failures. Below is an example simplified FMEA for programming infusion pumps that was used in an improvement project to reduce medication errors.

Putting It All Together: An Example Quality Improvement Project

The following is an example of how the QI methodology previously discussed could be used to address a practical problem. A hypothetical example of reducing medication errors in an anesthesiology department is described.

An anesthesia group was concerned over the large number of medication errors that were occurring in their department. They formed a multidisciplinary group including an anesthesiologist, nurse anesthetist, anesthesia resident, and pharmacist. They addressed the first question in the Model for Improvement—“What are we trying to achieve?”—by writing a SMART aim. Their SMART aim was to reduce medication errors in the Department of Anesthesiology from three errors per month to one error per month within 12 months.

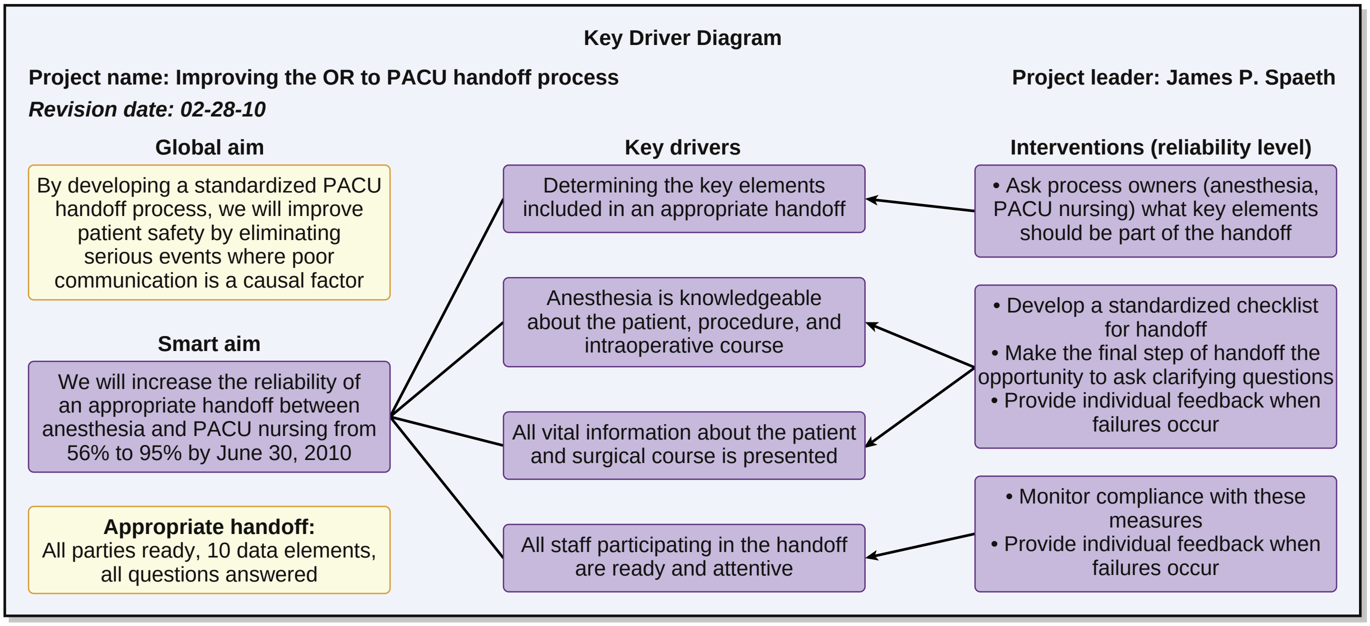
The next question in the Model for Improvement is “How will we know that a change will result in an improvement?” In order to monitor their progress, they constructed a run chart of medication errors per month in their department. They captured data through a previously existing self-reporting system.

The last question of the Model for Improvement is “What changes can we make that will result in an improvement?” To better understand the errors that were occurring, the group categorized the medication errors into categories and constructed a Pareto Chart. A Pareto Chart is a bar chart in which categories are listed in descending order. The group learned that three categories of errors accounted for about 80% of the total number of errors. These categories were infusion pump errors, acetaminophen errors, and antibiotic errors. They decided to focus their initial efforts on these three categories. They created process maps for these three categories to better understand the current process and develop possible interventions. Finally, to help organize their theory of improvement, they created a key driver diagram listing the drivers they thought would affect their aim, as well as possible interventions targeting the drivers.

Now that they had a theory of improvement, they started testing their interventions. They tested their ideas using PDSA cycles. They adopted the successful tests, adapted tests with mixed results, and abandoned the failed tests. Some of their tests included requiring a sticker from pharmacy and requiring a two-person double check of infusion pumps. As their testing and implementation continued, they saw the centerline, or median, of the run chart decrease from three to two. The run chart rules indicated this was a significant change. The group was excited that they had decreased the number of medication errors in their department, but they had not yet reached their aim of no more than one medication error per month. They decided to continue testing new ideas until the median decreased to less than one error per month.

Dashboards and Scorecards

A dashboard of measures functions like an instrument panel for an aircraft or automobile and provides real-time feedback on what is happening. Balanced *scorecards*, or “whole system measures,” are similar to dashboards and are used to provide a complete picture of quality. Developed by Kaplan and Norton, the balanced scorecard is defined as a “multidimensional framework for describing, implementing, and managing strategy at all levels of an enterprise by linking objectives, initiatives, and measures to an organization’s strategy.”[34] A set of measures should reflect the culture and mission of an organization. Viewed collectively, this set of measures provides a gauge of current performance and can also guide the direction for future organizational improvement efforts. A balanced set of measures is critical to ensure



Key Driver Diagram
Project name: Improving the OR to PACU handoff process
Project leader: James P. Spaeth
Revision date: 02-28-10
Global aim
By developing a standardized PACU handoff process, we will improve patient safety by eliminating serious events where poor communication is a causal factor
Smart aim
We will increase the reliability of an appropriate handoff between anesthesia and PACU nursing from 56% to 95% by June 30, 2010
Appropriate handoff:
All parties ready, 10 data elements, all questions answered
Key drivers
Determining the key elements included in an appropriate handoff
Anesthesia is knowledgeable about the patient, procedure, and intraoperative course
All vital information about the patient and surgical course is presented
All staff participating in the handoff are ready and attentive
Interventions (reliability level)
• Ask process owners (anesthesia, PACU nursing) what key elements should be part of the handoff
• Develop a standardized checklist for handoff
• Make the final step of handoff the opportunity to ask clarifying questions
• Provide individual feedback when failures occur
• Monitor compliance with these measures
• Provide individual feedback when failures occur

Fig. 5.4 Example of a key driver diagram developed to improve the operating room *(OR)* to postanesthesia care unit (*PACU*) handoff process. This diagram incorporates the global and smart aim of the project, the key drivers inherent to the process, and specific interventions targeting each of the key drivers. (From Boat AC, Spaeth JP. Handoff checklists improve the reliability of patient handoffs in the operating room and postanesthesia care unit. *Paediatr Anaesth.* 2013;23(7):647-654.)[93]

that improvement efforts in one area do not adversely affect outcomes in other areas.

Additional Quality Improvement Evaluation and Communication Tools

In most situations, QI frameworks such as the Model for Improvement or Lean Sigma are sufficient to help guide the development, testing, implementation, and spread of improvement. However, to better understand problems within a system or process, QI professionals have developed or adapted a number of methods and tools. Some of these methods and tools help with viewing systems and processes and organizing and communicating information. These are described in the following section.

Understanding how a process or system works is fundamental to improving it. Process mapping is a method to gain this understanding. A flow diagram, or flow chart, is an improvement tool used during process mapping; it provides a visual picture of the process being studied, wherein the series of activities that define a process is graphically represented. Flow charts identify and clarify all steps in the process. They also help the team understand the complexity of the process and identify opportunities for improvement.

Failure mode and effects analysis is a systematic, proactive method of identifying and addressing problems associated with a process. It uses a standardized approach to analysis that includes identifying the various steps in a process and addressing their failure modes, effects, and possible interventions.

A key driver diagram (KDD) (Fig. 5.4)[35] is another approach to organizing the theories and ideas for improvement that a team has developed. The KDD presents the aim or outcome of the project with both the theories (key drivers) behind the improvement and ideas for test of change.[7] Initially, the driver diagram helps lay out the descriptive theory behind the improved outcomes. As these theories are tested, the driver diagram is updated and enhanced to develop a predictive theory. KDDs are extremely useful because they provide a shared mental model for the team during its improvement efforts.

IMPROVEMENT INTERVENTION TOOLS

Efforts in QI and patient safety have produced tools with which to reorganize the way care is delivered. QI intervention tools are used to improve communication and teamwork. Examples of these tools include daily goals sheets, briefings/debriefings, and checklists.

Daily Goals Sheet

For nearly 20 years, documentation of daily goals as either a hand-written sheet or a whiteboard have been used to improve communication during multidisciplinary rounds in adult and pediatric ICUs.[36,37] As a one-page paper checklist, this tool would be completed every morning to establish the care plan, set goals, and review potential safety risks for each patient (Fig. 5.5).

Before implementation of the daily goals sheet in an adult ICU, an initial survey showed that ICU team members were unable to answer two simple questions after rounding at each patient's bedside: "Do you understand the patient's goals for the day?" and "Do you understand what work needs to be accomplished on this patient today?" Fewer than 10% of the residents and nurses knew the care plan for the day—a finding that was not surprising because traditional bedside rounds tended to focus on teaching the staff about disease processes rather than focusing on the work that was necessary to treat the patient. Approximately 4 weeks after the daily goals sheet was implemented, 95% of residents and nurses understood the goals for each patient. Moreover, after the daily goals sheet was implemented, length of stay in the

	Room Number _______________	Shift: ☐ AM / ☐ PM
Safety	What needs to be done to d/c patient from the ICU?	
	Patient's greatest safety risk? How can we ↓ risk?	
	What events or deviations need to be reported? ICUSRS issues?	
Patient Care	Pain & Sedation Management	Pain goal ____ /10
	Cardiac Review ECGs	HR goal ____ ☐ at goal ☐ ↑ ☐ ↓ β-blockade
	Volume status Net goal for midnight	Even ☐ Pos ☐ Neg ___ Net ___ (cc) ☐ Patient determined
	Pulmonary: Ventilator, ventilator bundle, HOB ↑, wean	☐ OOB/pulmonary toilet/ambulation
	SIRS/Infection/Sepsis evaluation Temp >38°C or <36°C; HR >90 RR >20 or $Paco_2$ <32 WBC >12000 < 4000 or >10% bands	☐ No current SIRS/sepsis issues ☐ Known/suspected infection ☐ Culture blood ×2/urine/sputum ☐ Antibiotic changes ☐ Discontinue sepsis bundle
	Can catheters/tubes be removed?	Y/N
	GI/Nutrition/Bowel regimen: TPN catheter, ND tube PEG needed?	☐ TPN ☐ NPO/Advance diet
	Is patient receiving DVT/PUD prophylaxis?	Y/N
	Can meds be discontinued, changed to PO, adjusted?	
To Do	Tests/Procedures today	
	Scheduled labs	
	AM labs needed/CXR?	
	Consultations	
Description	Has primary service been updated?	
	Has family been updated? Social issues addressed? Long-term/Palliative care	

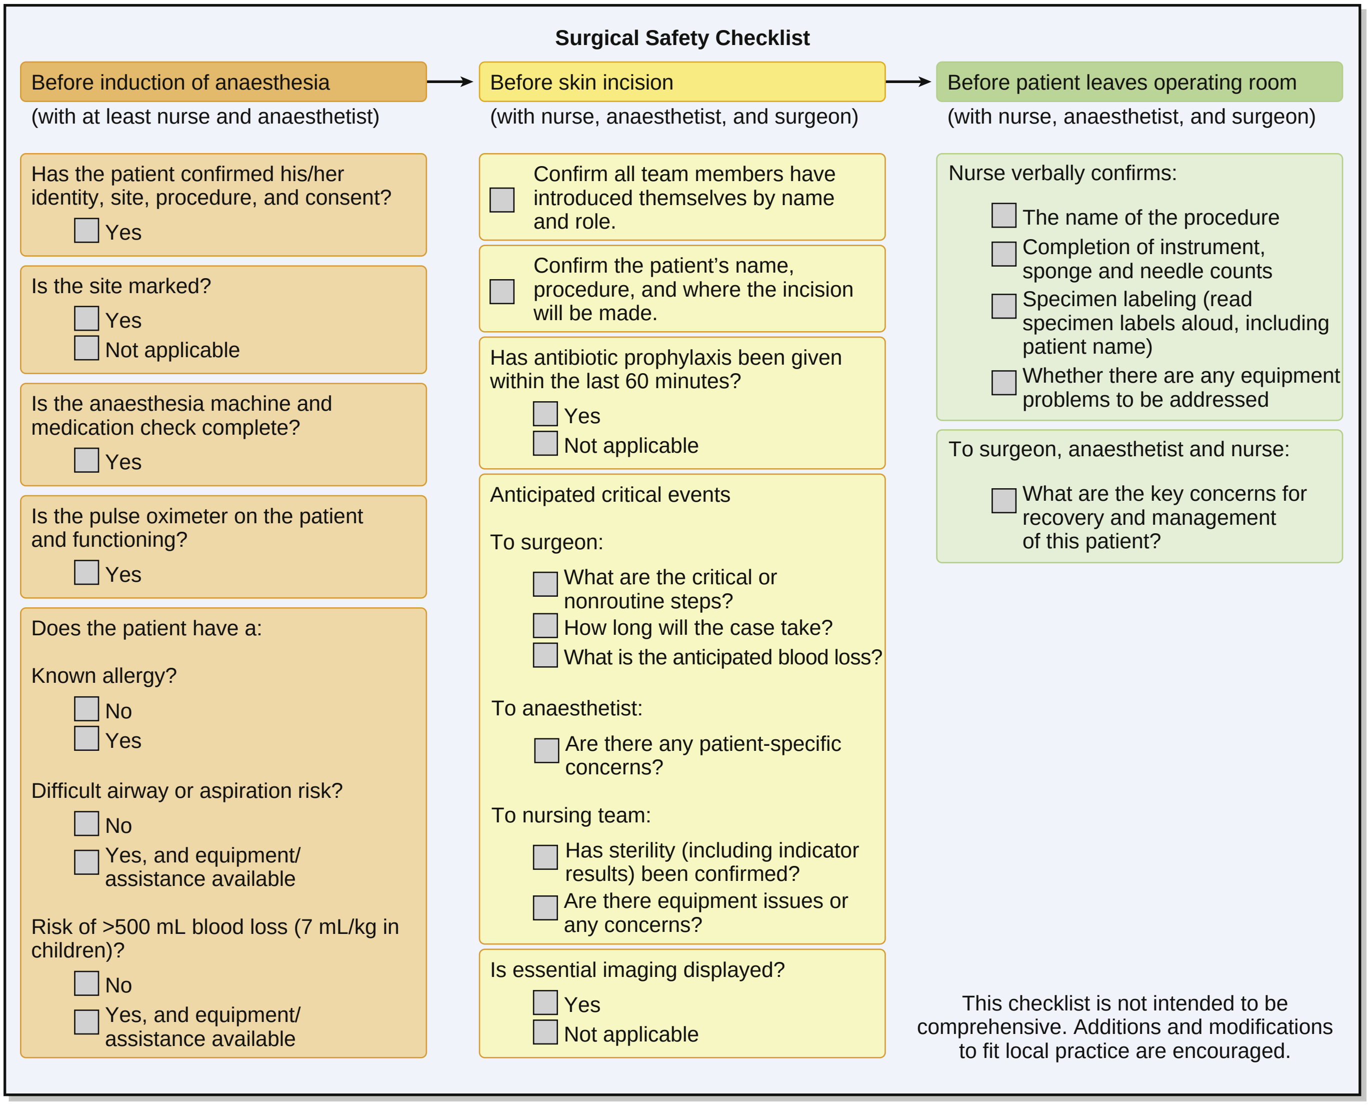
Fig. 5.5 Example of an intensive care unit *(ICU)* daily goals sheet. *CXR*, Chest radiograph; *d/c*, discharge; *DVT*, deep vein thrombosis; *ECG*, electrocardiogram; *GI*, gastrointestinal; *HOB*, head of bed; *HR*, heart rate; *ICUSRS*, ICU self-reporting system; *ND*, naso-duodenal; *NPO*, nothing by mouth; *OOB*, out of bed; *PEG*, percutaneous endoscopic gastrostomy; *PUD*, peptic ulcer disease; *RR*, respiratory rate; *SIRS*, severe infectious respiratory syndrome; *temp*, temperature; *TPN*, total parenteral nutrition; *vent*, ventilator; *WBC*, white blood cell count.

surgical ICU decreased from a mean of 2.2 days to only 1.1 days.[38] These results have been reproduced in ICUs with nurses, physicians, and pharmacists. Interviews supported that communication, patient care, and education were enhanced by providing a structured, thorough, and individualized approach to the patient's care. The daily goals checklist helped to identify new patient care issues and sparked management discussions, especially for sedation, weaning, and medications.[36] Additionally, a QI intervention using daily goals checklists in 118 ICUs in Brazil improved the use of low tidal volumes, avoidance of heavy sedation, use of CVCs, use of urinary catheters, perception of teamwork, and perception of patient safety climate, but did not reduce in-hospital mortality.[37]

A further improvement was implemented in a pediatric cardiac ICU using a whiteboard for visual display of the daily goals.[39] Use of the whiteboard increased the percent agreement among the patient care team for patient goals from 62% to over 87%.[37] The goals were updated as needed and used as an information source for all staff involved in the patient's care as well as for the patient's family. A daily goals display such as this can be modified for use on other nursing units or during OR sign-out or emergency department rounds.

Checklists

Checklists have been used in health care and other industries to ensure that important steps in a process are not forgotten. The Food and Drug Administration recommends that a checklist be used when checking out and inspecting an anesthesia machine before use to ensure that the equipment and monitors are functioning properly.[40,41] Checklists have been shown to be effective in reducing central line associated blood stream infections (CLABSI) by standardizing practice, reducing complexity, and providing a redundant safety check. The idea behind having a person, such as a nurse or another physician, be responsible for actually reading the checklist also empowers that person or anyone involved to stop the procedure if the checklist is not followed or if sterile technique is compromised. An early study showed that use of a central line insertion checklist and bundle resulted in a 66% reduction in the overall CLABSI rate; the median rate was reduced from 2.7 per 1000



Surgical Safety Checklist

Before induction of anaesthesia → (with at least nurse and anaesthetist)

Has the patient confirmed his/her identity, site, procedure, and consent?
☐ Yes

Is the site marked?
☐ Yes
☐ Not applicable

Is the anaesthesia machine and medication check complete?
☐ Yes

Is the pulse oximeter on the patient and functioning?
☐ Yes

Does the patient have a:

Known allergy?
☐ No
☐ Yes

Difficult airway or aspiration risk?
☐ No
☐ Yes, and equipment/assistance available

Risk of >500 mL blood loss (7 mL/kg in children)?
☐ No
☐ Yes, and equipment/assistance available

Before skin incision → (with nurse, anaesthetist, and surgeon)

☐ Confirm all team members have introduced themselves by name and role.

☐ Confirm the patient's name, procedure, and where the incision will be made.

Has antibiotic prophylaxis been given within the last 60 minutes?
☐ Yes
☐ Not applicable

Anticipated critical events

To surgeon:
☐ What are the critical or nonroutine steps?
☐ How long will the case take?
☐ What is the anticipated blood loss?

To anaesthetist:
☐ Are there any patient-specific concerns?

To nursing team:
☐ Has sterility (including indicator results) been confirmed?
☐ Are there equipment issues or any concerns?

Is essential imaging displayed?
☐ Yes
☐ Not applicable

Before patient leaves operating room (with nurse, anaesthetist, and surgeon)

Nurse verbally confirms:
☐ The name of the procedure
☐ Completion of instrument, sponge and needle counts
☐ Specimen labeling (read specimen labels aloud, including patient name)
☐ Whether there are any equipment problems to be addressed

To surgeon, anaesthetist and nurse:
☐ What are the key concerns for recovery and management of this patient?

This checklist is not intended to be comprehensive. Additions and modifications to fit local practice are encouraged.

Fig. 5.6 World Health Organization Safe Surgery Checklist. (Reproduced with permission from World Health Organization. WHO Surgical Safety Checklist.)

catheter days before the intervention to 0 by month 3 and through month 18 of the postintervention.[42] A central line insertion checklist has since been adopted by institutions, safety groups, and regulatory agencies as a tool to ensure compliance with the best practices for CVC placement and prevent CLABSI. Checklists and central line insertion bundles are widely available online; one such resource is the IHI (http://www.ihi.org).

In addition to standardizing technical tasks, checklists are also used to standardize communication. Haynes and colleagues[43] described the use of a checklist to guide the perioperative time-out, briefing, and debriefing process. They showed that implementing the World Health Organization Surgical Safety Checklist (Fig. 5.6) reduced mortality and inpatient complications.[43] The use of surgical checklists is now widespread and is standard of care in most OR settings around the world. Numerous studies related to surgical checklists either as a tool or a process have shown their effectiveness, while some studies have reported limited impact. A review of 25 highly cited research papers on surgical safety checklists from 2009 to 2016 showed the complexity of standardizing, implementing, and sustaining the use of surgical safety checklists.[44] Complexities include variations in the environment, distribution of staff, timing of when the checklist is actually used, relationship between those using the checklist, and the culture of the institution.[44] These complexities may undermine the effectiveness of checklists and should be considered prior to checklist implementation.

Briefings and Debriefings

The surgical checklist is part of the Universal Protocol, which was created to prevent wrong person, wrong procedure, and wrong site surgery. In order to address many of the other important safety issues, such as antibiotic needs, deep vein thrombosis prevention, fire prevention, special equipment needs, and blood product availability, many institutions have implemented OR briefings or huddles, as well as debriefings at the end of surgery. Preoperative briefings have been shown to improve team communication, improve compliance with best practices, and enhance the overall perception of the safety climate in the OR.[45]

Briefing and debriefing tools are designed to promote effective interdisciplinary communication and teamwork.

	Briefing: Before Every Procedure
	Team introductions: First and last names, including roles; write names on board
	Verify: Patient ID band, informed consent (read out loud), site marking, OR posting, patient's verbalization of procedure (if patient awake), H&P or clinic note
	Are there any safety, equipment, instrument, implant, or other concerns?
	Have antibiotics been given, if indicated?
	What are the anticipated times of antibiotic redosing?
	Is glucose control or β-blockade indicated?
	Is the patient positioned to minimize injury?
	Has the prep solution been applied properly, without pooling, and allowed to dry?
	Have the goals and critical steps of the procedure been discussed?
	Is the appropriate amount of blood available?
	Is DVT prophylaxis indicated? If yes, describe.
	Are warmers on the patient?
	Is the time allotted for this procedure an accurate estimate?
	Have the attendings reviewed the latest laboratory and radiology results?
	Debriefing: After Every Procedure
	Could anything have been done to make this case safer or more efficient?
	Has the Surgical Site Infection data collection form been completed?
	Are the patient's name, history number, surgical specimen name, and laterality on the paper work? (must be independently verified by the surgeon)
	Did we have problems with instruments? Were they reported?
	Plan for transition of care to postop unit discussed? ❒ Fluid management? ❒ Blood transfusion paperwork in chart? ❒ Antibiotic dose and interval to be continued postop? ❒ Pain management/PCA plan? ❒ New medications needed immediately postop? ❒ β-blockers needed? ❒ Glucose control? ❒ DVT prophylaxis?

Fig. 5.7 Example of an operating room briefing and debriefing tool. *DVT,* Deep vein thrombosis; *H&P,* history and physical; *ID,* identification; *OR,* operating rooms.

Both have been used in the OR, during sign-out from the ICU nursing staff to the intensivist, and between OR nursing and anesthesia coordinators.[40,46,47] A briefing is a structured review of the case at hand that takes place among all team members before the start of an operative procedure. A debriefing occurs after the procedure; the team reviews what worked well, what failed, and what could be accomplished better in the future (Fig. 5.7).

An example of an OR briefing includes introduction by name (first and last) and role of each team member, confirmation of the correct patient, confirmation of the site/side and procedure (time-out), and a verbal assurance that all team members agree that they understand the procedure and what is required to ensure its success. A check of all necessary equipment, medications (e.g., appropriate antibiotic), and blood availability is performed. The question, "If something were to go wrong, what would it be?" is asked, and plans to mitigate or respond to the potential hazard are discussed.

A collaborative effort by the Agency for Healthcare Research and Quality (AHRQ) and the Department of Defense adopted crew resource management strategies for OR briefings and produced an evidence-based resource called Team Strategies and Tools to Enhance Performance and Patient Safety (TeamSTEPPS) www.ahrq.gov. This team approach in the OR encourages situational awareness and communication among all members of the healthcare team.[48-51]

Sources of Quality Improvement Information

Development of a QI project first requires that an issue be identified. Baseline data are then collected and an improvement intervention instituted, often using one of the approaches described earlier. Data are re-collected after the intervention. If the intervention is found to be effective, ongoing monitoring or audits are instituted to ensure that the change is sustained. As part of the audits, feedback must be given to the providers. Healthcare providers traditionally have had limited ability to obtain feedback regarding performance in their daily work, in part because of a lack of information systems and a lack of agreement on how to measure quality of care.[52]

Ideas for QI projects can be identified from a multitude of sources, but they typically start with surveys and input from local medical staff and reviews of reported incidents. Additional information is gathered from the literature, review of national guidelines and quality metrics, and information obtained from external or internal reviews.

Sources of QI data that span both the clinical and administrative arenas include evidence-based medicine and evidence-based clinical practice guidelines, alerts from accrediting agencies and nonprofit safety organizations, standards and guidelines put forth by medical specialty associations, closed claims databases, and government agency administrative databases. United States governmental agencies, including the AHRQ, CMS, and the National Quality Forum (NQF), promote the development and reporting of healthcare quality measures.[53]

INCIDENT REPORTING

Voluntary incident reporting capturing hazardous conditions has been successfully used to improve patient care and foster QI programs.[54] As the potential of voluntary incident reporting is being realized in health care, this reporting has become less punitive and more focused on systems rather than on individuals. Voluntary incident reporting, when appropriately applied, helps identify hazards to patients that can then become the focus of QI efforts that seek to mitigate those hazards.[55] Unlike other methods that evaluate harmed patients, voluntary incident reporting provides the potential to also learn from near misses—incidents that did not lead to harm but were potentially hazardous. These near misses and potential hazards are a rich source for QI projects highlighting the importance of preventing harm.

All anesthesiology departments should have a process in place for capturing adverse events and near misses. Although most departments have a process for reporting, many incidents go unreported for a variety of reasons. Departments should encourage voluntary reporting without threat of punishment. Electronic capture of adverse events, near misses, and complaints can provide data that can subsequently be analyzed to identify trends and assess the degree of harm that a hazard poses to patients.

Events that occur frequently with low harm can be just as important as an event that occurs rarely with high harm. At the local level, it is more effective to focus on a more frequently occurring adverse event (e.g., perioperative skin abrasions, mislabeling of laboratory specimens) or on a process that can be measured with high frequency (e.g., hand hygiene, administration of antibiotic prophylaxis). For rarely occurring harmful events, a QI initiative may encompass a more expansive analysis of a national adverse-event database with multicenter participation.

With multiinstitutional event reporting systems, events that would rarely be seen in a single institution can be collected in larger numbers. Such systems allow analysis for common causes that increase our knowledge base for prevention initiatives. Larger multiinstitutional data gathering systems include the Vizient collaborative (the former University HealthSystem Consortium), which supports event reporting and databases that can be used to develop QI programs, benchmarking, and evidence-based practice.[56] Reporting systems that have been developed specifically to investigate rarely occurring anesthesia-related events include the Anesthesia Incident Reporting System (AIRS) created by the Anesthesia Quality Institute (AQI)[57] and Wake Up Safe, a QI initiative of the Society for Pediatric Anesthesia.[58] The AIRS program publishes a learning case each month in the *ASA Newsletter,* including a summary of a reported case with learning points.

More expansive international incident-reporting systems that are anonymous and voluntary have also been analyzed in the literature and have provided important information. Examples are the United Kingdom's Serious Incident Reporting and Learning Framework[59] and the Australian Incident Monitoring Study.[60] These incident registries do not require that the events be considered human error or preventable to merit reporting and are a source of ideas for QI projects.

Although voluntary systems often prove fruitful, many events and near misses still frequently go unreported. One way to capture these incidents is to survey local medical staff members to obtain their thoughts on how the last patient was harmed or how the next patient might be harmed. This process of performing a staff safety assessment survey is described in two later sections of this chapter (see "Collaborative Programs" and "Comprehensive Unit-Based Safety Program"). Staff safety assessment surveys can be particularly helpful for identifying issues for QI projects. Additionally, if staff members identify the issue, the likelihood is greater that they will have a vested interest in participating in the QI efforts.

PUBLISHED LITERATURE

Literature reviews offer ideas for QI topics in specific areas and information to guide interventions. For example, if the QI project plan is to reduce hazards in cardiac anesthesia, a literature review will provide reports of various cardiac anesthesia risks. Once a topic within a clinical area is selected, a literature search should be performed again to determine whether similar QI projects have been performed and whether they were successful. Such information will help with the design of a future initiative. The literature also provides published reports that identify guidelines and/or evidence-based practices that can be the basis for future programs.[61,62]

NATIONAL INITIATIVES AND QUALITY METRICS

The AHRQ is the source for both the U.S. National Quality Measures Clearinghouse and the National Guideline Clearinghouse. Professional organizations, such as the American Society of Anesthesiologists (ASA) and the World Federation of Societies of Anesthesiologists, offer field-specific guidelines. The ASA has supported the review and development of many important guidelines that can serve as a rich source of QI initiatives. These guidelines cover a range of practices and include guidelines for the placement of central venous access,[63] management of patients with obstructive sleep apnea,[64] and management of preoperative fasting.[65] For those who are also involved in critical care medicine, guidelines and protocols do improve performance with specific care processes such as sedation and ventilator weaning protocols in ICUs. Such protocols decrease the duration of mechanical ventilation and ICU length of stay.[66,67]

Review of national quality metrics is another source of ideas for QI topics. National initiatives from CMS, such as the QPP (described earlier in "Quality Improvement Measures and Tools") and Surgical Care Improvement Project (SCIP), provide quality metrics and are associated with pay for performance. Most of the SCIP measures, which predominantly

TABLE 5.3 Nonprofit and Governmental Quality Improvement Organizations Pertinent to Anesthesia

Medicare Quality Improvement Community (MedQIC)	www.medquic.org	A national knowledge forum for health care and quality improvement professionals
National Quality Forum	www.qualityforum.org	Created to develop and implement a national strategy for health care quality and reporting
National Patient Safety Foundation (NPSF)	www.npsf.org	An independent 501(c)(3) organization with a mission to improve the safety of patients

measure processes of care, are topped out (nearly 100% in all hospitals) and have therefore been retired from active surveillance. The Joint Commission (TJC) website (www.jointcommission.org) lists United States National Patient Safety Goals and national quality core measures that are surveyed during site visits for accreditation. In 2004, TJC partnered with CMS to align measures common to both organizations in an initiative called Hospital Quality Measures. These measures are also endorsed by the NQF, a private, nonprofit membership organization created to develop and implement a national strategy for healthcare quality measurement and reporting (www.qualityforum.org). One of NQF's functions is to endorse quality and safety measures (consensus standards), which are then incorporated into other national quality initiatives. The goal for NQF-endorsed standards is that they become the primary standards used to measure the quality of health care in the United States. Increasingly, anesthesia programs are focusing on the standards that are relevant to the specialty because facilities are being evaluated on compliance with regulations and are required to report their performance regarding these standards to the governing bodies.

An increasing number of regional and national organizations are developing initiatives that are stimulating the reporting of specific evidence-based practices and outcomes. These initiatives are also determining the local selection of areas for QI (Table 5.3). As described earlier, reporting of these measures to CMS is being incentivized by performance-based payment. National professional organizations such as the ASA are developing metrics specific to the field.

OUTCOMES RESEARCH

The comparison of outcomes associated with different process decisions, or variations in care delivery, is the basis for outcomes research. Outcomes research offers a potential to identify these variations in care and to determine whether they improve outcomes for patients undergoing anesthesia. One of the key issues in outcomes research is risk adjustment, a challenging goal that requires a robust dataset. Using administrative data to identify patient risk factors has many limitations.[68] Registries designed specifically for research, benchmarking, and QI are good sources for this purpose.

The Society of Thoracic Surgeons (STS) and the National Surgical Quality Improvement Programs (NSQIP) are examples of outcomes research registries. Established in the early 1990s, the STS database now includes participation by nearly all U.S. cardiac surgery centers and has developed robust risk-stratification models. Findings from this database have led to initiatives associated with significant reductions in mortality; examples include the use of β-adrenergic blockers and aspirin perioperatively and the use of internal mammary arteries for coronary artery bypass grafting. NSQIP is a newer registry that was developed by the U.S. Department of Veterans Affairs (VA). Findings from this risk-adjusted outcomes database were used to identify variations in care. The changes that were instituted based on these findings resulted in improved surgical outcomes throughout the VA network. NSQIP has been adopted by the American College of Surgeons to provide comparisons among hospitals. Currently, more than 350 general surgery centers participate.[69] Hospitals that participate submit detailed data on a sample of general surgical patients for a number of common surgical procedures. They then receive a graphic display that compares their outcomes with those of the entire cohort. Surgery centers then use these data to identify areas in which they might be able to make improvements and initiate QI projects with that focus. As an example, the Kaiser Permanente group used this information to develop a QI program focused on reducing the percentage of patients with prolonged perioperative intubation.[69]

The ASA created the AQI and the National Anesthesia Clinical Outcomes Registry with the goal of improving anesthesia outcomes through capture of case-specific data directly from electronic anesthesia data systems.[70,71] These resources are still evolving and moving forward to improve outcomes in anesthesia. Another important effort in anesthesia is the Multicenter Perioperative Outcomes Group (MPOG), which is led by researchers at the University of Michigan.[72] MPOG has established a national network of anesthesia practice groups that contribute data to a unified database. The goals of MPOG are to develop a structure for multiinstitutional collaboration and data sharing, to develop the information technology infrastructure to pool a wide variety of perioperative data for patient-centered research, to develop the statistical infrastructure to analyze the data, and to provide an academic venue in which faculty from multiple institutions will be able to collaborate in outcomes research (http://mpog.med.umich.edu).[72]

INTERNAL OR EXTERNAL INSTITUTIONAL REVIEWS

Internal or external institutional reviews of healthcare processes can provide important insights and ideas for QI initiatives. In addition to the external regulatory reviews, institutions are expected to perform internal reviews of quality and identify areas for improvement. These reviews are often used for QI projects at the institutional level.

Examples of Quality Improvement Programs

Examples of QI frameworks and tools have been discussed. This section addresses broad initiatives for quality and safety improvement that have used some of the methodologies and tools detailed earlier in this chapter.

COLLABORATIVE PROGRAMS

Use of a collaborative is one approach to improving broad areas of care. A QI collaborative involves the participation of two or more healthcare teams working toward a shared goal. In healthcare, a set of multidisciplinary representatives (from all of the clinical and administrative areas that are linked to the area of focus) should participate in the collaborative. A collaborative can be developed within a single organization and/or across multiple healthcare organizations. Collaborative programs are typically led by a team that is responsible for the following:

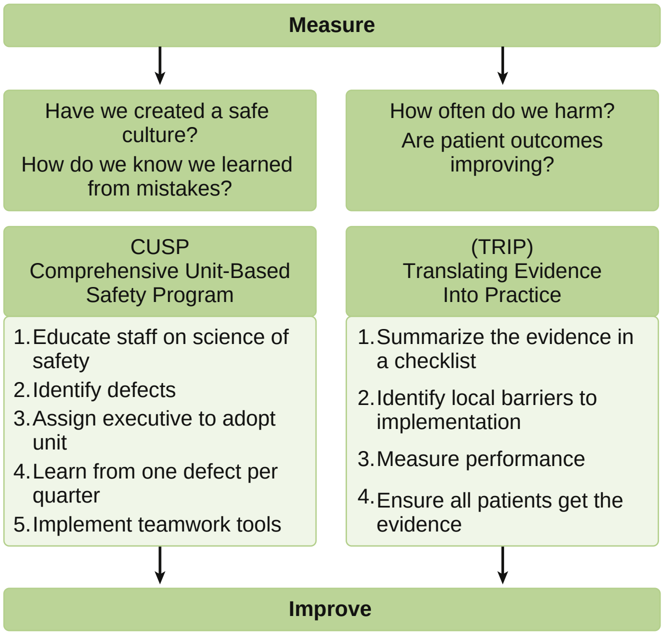
1. Determining the evidence-based interventions to be used and presenting these to the participants (if evidence-based interventions are not available, the team will generate interventions based on local and broad expert consensus)
2. Establishing the data collection approach (defining measures, collection methods, and feedback mechanism)

A key element to the success of collaboratives is an established process for educating members and for sharing interventions and obstacles. Through group discussions (meetings and/or conference calls), teams can learn about best practices and innovative methods used by other teams to approach a problem. In addition, collaboratives bring a shared momentum and enthusiasm that can increase sustainability.[24,73,74]

INSTITUTE FOR HEALTHCARE IMPROVEMENT BREAKTHROUGH SERIES COLLABORATIVES

QI collaboratives provide an opportunity to learn from other teams, work collaboratively, and spread change on a larger scale. The IHI has used a collaborative model for improvement, called the Breakthrough Series Model, for more than a decade. Collaboratives run from 12 to 160 teams across multiple organizations. Successful IHI collaboratives have included reducing waiting times by 50%, reducing ICU costs by 25%, and reducing hospitalizations of heart failure patients by 50%.[75]

In the Breakthrough Series Model, a topic is selected and participating teams are enrolled (Fig. 5.8). Expert faculty from across the country, or even internationally, are recruited for an expert meeting to develop a framework for change called a "change package." The change package describes interventions for improvement based on available evidence. Next, team members from all groups attend collaborative learning sessions where they learn the model for improvement and share their progress implementing the change package. At the end of the collaborative, a summative meeting and publications are used to share the findings with others.



Measure
Have we created a safe culture?
How do we know we learned from mistakes?
How often do we harm?
Are patient outcomes improving?
CUSP
Comprehensive Unit-Based Safety Program

Using evidence, rigorous measurement, and collaboration to eliminate central catheter-associated bloodstream infections. *Crit Care Med.* 2010;38:S292–S298.)

COMPREHENSIVE UNIT-BASED PROGRAM

Sawyer and associates reported the success of a collaborative that incorporates a "mechanism to move evidence to the bedside and foster a culture where the focus is the patient."[76] The collaborative includes an emphasis on translating evidence into practice (TRIP) and the Comprehensive Unit-Based Safety Program (CUSP). This methodology has been reproduced and validated in several large collaborative efforts (Fig. 5.9).[76-78]

The TRIP model incorporates the following key steps and emphasizes the importance of measurement and feedback of data to teams.

1. Identify evidence-based interventions associated with an improved outcome through review of peer-reviewed publications.
2. Select goal-oriented interventions that have the most impact on outcomes and transform them into behaviors. In selecting behaviors, focus on interventions with the strongest treatment effect (smallest number needed to treat) and the lowest barrier to use.
3. Develop and implement measures that evaluate either the interventions (processes) or the outcomes.
4. Measure baseline performance and establish databases to facilitate accurate data management and timely feedback to teams.
5. Ensure that patients receive evidence-based interventions through four basic steps: engagement, education, execution, and evaluation (Table 5.4).

The format for the collaborative also includes annual face-to-face meetings with the participating teams and periodic conference calls, which focus on education about the actual processes being implemented, the evidence base to support these processes, and the sharing of experiences. First, weekly immersion calls provide an initial overview of the program, describe the roles and responsibilities of each of the individuals, and introduce the tools that are to be used. Once the collaborative is introduced, monthly content calls are held throughout the program and are typified by a slide presentation of the evidence base for the intervention or of other components of the program to be implemented. The monthly coaching calls offer an opportunity for teams to share how well or how poorly they are implementing the interventions and share ideas for overcoming barriers.

TABLE 5.4 Four Steps That Ensure Patients Receive Evidence-Based Interventions Through a Collaborative Using the Example of Catheter-Related Bloodstream Infections

Step	Action	Example
Engage	Make the problem real	Share information of local CRBSI rate vs. national rate
Educate	Develop an educational plan to reach ALL members of the caregiver team	Present evidence-based practices at grand rounds and multidisciplinary team meetings Present plans to improve care and measure outcome
Execute	Develop a safety culture Reduce complexity of the processes Introduce redundancy in processes Hold regular team meetings	Develop a culture of intolerance for CRBSI Ensure that all equipment and supplies for sterile CVC insertion are in one place and easily available Use checklists that identify key steps to reduce CRBSI Focus on one to two tasks per week and identify team member responsible for task
Evaluate	Measure and provide feedback	Develop data collection plan and database to track progress Give staff real-time feedback; post progress in highly visible location Identify causes of defects

CRBSI, Catheter-related bloodstream infections; *CVC*, central venous catheter.

Inclusion of the CUSP program in the collaborative provides a structured approach to improve safety culture and identify and mitigate hazards (i.e., learn from mistakes).[38,47] CUSP is a five-step program that has been tested and used successfully to improve quality and safety in ICUs (Table 5.5).[79,80] CUSP programs have been used in many different environments including inpatient units, primary care practices,[81] and in the perioperative period[82] to enhance the safety culture and improve the patient experience.[83]

Safety culture is assessed before the implementation of CUSP and reassessed after 1 year to evaluate the impact of the program. Multiple culture assessment tools are available.[64,65] The AHRQ offers a free survey online (www.ahrq.gov). The initial measure provides a baseline assessment of staff perceptions of safety culture in their clinical areas and their perceptions of the organization's commitment to patient safety.

Education is a crucial aspect of CUSP; it provides staff with a new set of lenses through which to identify hazards and

TABLE 5.5 Five-Step Comprehensive Unit-Based Safety Program

	Step	Description
1	Present educational material	Educate staff on science of safety though lectures and other educational materials
2	Complete forms that identify patient safety issues	Ask the following questions: ▪ How will the next patient be harmed? ▪ How can this harm be prevented? ▪ Establish voluntary incident reporting
3	Assign senior executive responsible for specific area	Senior executive meets with all staff of the clinical area to: ▪ Help prioritize safety efforts ▪ Remove barriers for system changes ▪ Provide resources ▪ Demonstrate hospital commitment to patient safety ▪ Foster relationship between senior leadership and staff
4	Learn from defects	Implement projects focused on two to three safety issues Keep goals simple: ▪ Reduce complexity in the process ▪ Create independent redundancies to ensure critical steps are accomplished
5	Implement teamwork tools	Implement programs such as checklists, training, and daily goals targeted at improving teamwork and communication

recommend system changes to improve care. The objectives of these educational efforts are to ensure that staff: (1) understand that safety is a system property, (2) learn concepts for reliable healthcare design, and (3) understand the basics of change management. After an educational lecture on the science of safety, staff members are requested to identify patient safety hazards in their clinical areas and suggest improvement interventions. For this process, staff members review incident reports, liability claims, and sentinel events from their unit. In addition, two questions are asked: "How do you think the next patient will be harmed?" and "How can we prevent it from happening?"

After the completion of the survey and educational component, a senior leader of the institution (e.g., hospital president, vice president, director) is partnered with a unit or clinical area. This leader attends rounds on the unit monthly to help staff members prioritize safety efforts, to ensure that they have the resources to implement improvements, and to hold them accountable for evaluating whether safety has improved. Staff members are asked to learn from one defect per month and to implement one tool per quarter designed to improve care delivery.[38,47]

CUSP was pilot-tested in ICUs and subsequently implemented throughout Johns Hopkins Hospital and in the Michigan Keystone project.[77] In the pilot, a patient-safety team that consisted of staff from the clinical area was responsible for oversight of the program. To be most effective, this team included the ICU director as the ICU physician safety champion, the nurse manager, another ICU physician and nurse, a risk manager or patient-safety officer, and a senior executive from the institution. The program worked best if the physician and nurse who led the program dedicated at least 20% of their time to improving quality and patient safety. The first unit was the beta site; subsequent teams from other clinical areas would learn from its successes and failures. The ultimate goal was to have every area in the hospital organizing and managing safety through CUSP.

CUSP has been associated with significant improvements in safety culture. The percentage of staff reporting a positive safety climate increased from 35% before CUSP to 60% after CUSP.[80,84] In addition, teams identified and mitigated several specific hazards through CUSP. As a result of asking staff members to speculate on how the next patient might be harmed, the ICU created a dedicated ICU transport team, implemented point-of-care pharmacists, implemented the daily goals sheet, clearly labeled epidural catheters to prevent inadvertent intravenous connection, and standardized the equipment in transvenous pacing kits.[85] Moreover, the use of CUSP decreased the length of stay and nurse turnover.

In summary, CUSP provides several benefits for improving safety culture and is a primer for staff compliance in implementing any safety or QI intervention or project. It provides enough structure to convert the often-vague goals of improving safety into a focused strategy; yet it is flexible enough to allow units to work on issues most important to them. CUSP provides a venue to introduce rigorous research methods, acts as a learning laboratory to identify and mitigate hazards, and has the potential to improve patient outcomes.

CHALLENGES AND BARRIERS TO QUALITY IMPROVEMENT PROJECTS

Multicentered and/or single-hospital projects can fail because of inadequate resources, lack of leadership support, vague expectations and objectives for team members, poor communication, complex study plans, inadequate management of data collection, and wasted efforts to "reinvent the wheel" rather than adopting practices proven to be effective. Successful collaboratives require a local culture (the set of values, attitudes, and beliefs of the group) that is ready for change and participants who have a shared view of safety and who understand the science of patient quality and safety (i.e., the technical components of how care is organized and delivered).

RELATED CONCEPTS: IMPROVEMENT SCIENCE AND IMPLEMENTATION SCIENCE

The focus of this chapter has been QI operations, or the efforts concerned with the measurement and timely improvement of quality in a given setting. QI operations is related to improvement science and implementation science, both of which aim to create generalizable knowledge that has the potential to improve care quality and patient outcomes across settings. These three fields are often confused because they share tools and are all interested in improving patient outcomes, but may use different terms to refer to similar concepts. To provide clarity about the similarities and differences between these fields, Koczwara and colleagues conceptualized a spectrum with QI operations at one end, implementation science at the other, and improvement science in the middle.[86] Understanding the roles for these fields may prove useful to those interested in anesthesia QI.

QI operations. As described at length in this chapter, QI is the systematic approach to improving problems in healthcare delivery that compromise care quality and outcomes. It is a timely, context-dependent team endeavor that has the potential to improve local care in the short, medium, and long term.

Improvement science. A common criticism of QI is that it is "unscientific" and more concerned with action than with understanding the mechanisms through which improvement occurs (or the reasons underlying the failure of improvement efforts). Improvement science draws from QI principles, aiming to "create practical learning that can make a timely difference to patient care."[87] But improvement science is also concerned with the creation of generalizable knowledge. Hence, close attention is paid to both internal and external validity in the design of improvement studies. Rigorously designed improvement science projects may sacrifice some of the timeliness of QI projects, but balance this downside with greater potential utility of the findings outside of a local setting.

Implementation science. Implementation science (known as knowledge translation in Canada) aims to narrow the evidence-to-practice gap evident when proven-effective interventions do not translate into improved care and outcomes.[88] Although the field is characterized as a new one, it draws from psychology, education, management, and related sciences. Two features clearly distinguish implementation science from QI and improvement science: the reliance on evidence-based practices and the use of explicit frameworks, theories, and models. Implementation science is a major focus for research funding agencies in the United States and Canada, as it is seen as one approach to maximize the return on grant dollars allocated to scientific discovery in health care. As with QI and improvement science, the adequate characterization of "real world" contexts is paramount. In contrast, there tends to be greater emphasis on generalizability in implementation science as compared to improvement science.

A key distinction between these three fields is their relationship to evidence. Implementation science relies on evidence-based interventions. However, there is not always evidence to guide our practice in situations with clearly suboptimal quality. In these situations, QI approaches can be useful, as rapid-cycle small-scale tests of change can minimize harm and mitigate risk at the same time as quality is addressed.

The Future: Research, Education, and Ethics

Much remains to be accomplished in QI. The opportunity to improve patient care is substantial, and the pressure to improve the quality of perioperative care continues to increase. Improving quality of care requires the ability to measure and improve performance. Research is needed to develop measures of quality that clinicians believe are valid and to learn how to ensure that all patients reliably receive recommended interventions. Innovation is needed to develop information systems that can be used by multiple disciplines. Anesthesiologists and professional societies may need to partner with experts in quality measurement to develop and implement quality measures. Future efforts should balance the feasibility and validity of quality measures and develop integrated approaches to improving quality, including strategies to develop care bundles, decrease complexity, and create independent redundancies.

TABLE 5.6 Accreditation Council of Graduate Medical Education (ACGME) Six Core Competencies and Institute of Medicine (IOM) Six Aims for Improvement

	ACGME Core Competencies	IOM Aims for Improvement
1	Patient care	Safe
2	Medical knowledge	Timely
3	Interpersonal and communication skills	Effective
4	Professionalism	Efficient
5	System-based practice	Equitable
6	Practice-based learning and improvement	Patient-centered

Clinicians now need the skills necessary to improve quality. Health care will cross the quality chasm only when all view quality and safety as their primary job, rather than as an added activity, and healthcare organizations provide the infrastructure to monitor and improve performance. Frontline healthcare providers must understand the science of quality and safety and evaluate safety risks as hazardous systems, not incompetent people. Integral to this is the education of our trainees. CQI in anesthesia residency training programs has been touted for more than 25 years.[89] In the United States, residents in training are expected to master six core competencies, as mandated by the Accreditation Council of Graduate Medical Education,[90] competencies that are linked to the NAM's six Aims for Improvement (Table 5.6).[3] In an effort to link these two sets of goals and apply them to the clinical setting for training purposes, Bingham and colleagues[91] developed a framework called the Healthcare Matrix that can be used as both an educational tool and a research tool for improvement.

With the increasing amount of intellectual focus and healthcare resources being directed toward QI programs, the ethics of QI have come to light. QI projects have generally been exempt from the rigorous review of human-subjects research. However, a Hastings Center Report on the ethics of using QI methods to improve health quality and safety suggests that some QI projects may involve risk to patients and should undergo a formal review.[92] This report lists QI initiatives that may trigger the need for a review as those that have a randomized design, use novel treatments, involve researchers, have delayed feedback of monitoring, or are funded by external sources. The reporting of QI activities should be encouraged, as should requiring approval by an internal review board and following a standardized format for reporting the results. All of these practices support the premise that delivery of quality care is a science as well as an art.

Summary

Healthcare organizations need a systematic approach to three areas of patient safety: (1) TRIP, (2) identifying and mitigating hazards, and (3) improving culture and communication. The underlying principle for all of the approaches discussed in this chapter is that improvement of the quality of care dictates that practitioners must be able to measure their performance. Healthcare practitioners traditionally have had limited ability to obtain feedback regarding performance in their daily work, in part because of the absence of information systems and a lack of agreement on how to measure quality of care.[44] As a result, many in health care do not have access to performance data and consequently do not know what results they achieve (or fail to achieve). As consumers, payors, regulators, and accreditors increasingly require evidence regarding quality of care, the demand for quality measures will grow. To meet these demands, anesthesiologists must be prepared to use valid measures to evaluate the quality of care that they provide and to implement evidence-based best practices in the perioperative care of patients.

Acknowledgments

The editors and the publisher would like to acknowledge Dr. Elizabeth Martinez (b. 1966–d. 2013) for her contributions to previous editions of this chapter. Her work served as the foundation for the current chapter.

This chapter greatly benefited from the thoughtful editing of Claire Levine.

Avoiding Patient Harm in Anesthesia: Human Performance and Patient Safety

STEPHANIE MARIA OBERFRANK, MARCUS RALL, PETER DIECKMANN, MICHAELA KOLBE, and DAVID M. GABA

KEY POINTS

- Excellent clinical performance is not achieved by the use of sound medical knowledge alone, as clinicians have to face multifaceted challenges not just medical issues. There is an increased awareness that human factors—both on the individual and the team level—as well as organizational factors in the health care system play major roles in providing excellent medical care. Therefore, for anesthesia professionals (1) the study of human performance is fundamental, (2) the knowledge and successful application of efficient safety strategies are highly relevant, and (3) understanding of the pertinent organizational matters is very important.
- The health care system in general, individual clinical institutions, and work units in particular must provide the appropriate organizational characteristics to facilitate safe patient care including: promoting a culture of safety, effective incident reporting and analysis systems, continuous training for professionals, and optimized structures and processes.
- Organizations that provide such characteristics are referred to as high-reliability organizations (HRO). HRO theory describes the key features of systems that conduct complex and hazardous work, but do so with extremely low failure rates and complications. The credo of HROs is not to erase all errors but rather to identify human error mechanisms and make systems more impervious to errors and their sequelae (resilience).
- Several mechanisms of optimal versus poor performance have been demonstrated through human performance research. A particular technique of human performance research called task analysis has been useful in understanding the work of anesthesia professionals. Observing them during routine operations or in the handling of (simulated) adverse events has improved our knowledge on human performance. The findings include the impact of critical and continuous situation awareness and decision making (i.e., core cognitive process model), effective teamwork, leadership, and communication, as well as task management and the use of cognitive aids (e.g., checklists or emergency manuals).
- Organizations and individuals need to fully recognize that the performance of individual anesthesia professionals can—as for all human beings—be adversely influenced by performance-shaping factors, including noise, illness, aging, boredom, distraction, sleep deprivation, and fatigue, as well as by social dynamics within and between crews and teams.
- It is necessary to have a clear understanding of known human performance pitfalls such as fixation errors, ineffective team communication, misunderstandings, medication errors, unclear task management, and erroneous assumptions. While anesthesia professionals' knowledge and skill are key strengths needed for safe patient care, addressing the limitations will help them to actively avoid or mitigate the risk of adverse events.
- One approach to understanding and intervening in human performance issues for anesthesia care, especially focused on challenging situations, is that of crisis resource management (CRM). CRM (as in "cockpit [then crew] resource management") was developed in aviation first but then adapted to health care, initially for anesthesia care, in the early 1990s. There are many formulations of CRM but they typically highlight situation awareness, dynamic decision making, task management, communication, and teamwork. The introduction of CRM in anesthesiology and its spread into many other health care disciplines and domains have typically been associated with the use of realistic simulation-based training of anesthesia professionals in single-discipline or combined team training. It also has helped focus attention on systems' issues that relate to key aspects of human performance highlighted in CRM-oriented training.

- "First do no harm": Every avoidable harm or death to a patient is one tragic event too many. Anesthesia professionals must strive to avoid all harm that they may potentially impose, knowingly or not, on patients. Future progress on patient safety and human performance in anesthesia will require interdisciplinary research and training, improvements in systems thinking and systems safety, organizational learning, and the involvement of all levels of the health care industry.

What this Chapter is About: An Overview

This chapter provides the reader with an overview of key human performance and safety issues concerning anesthesiology and demonstrates the relevance of those topics to the clinical performance of anesthesia professionals. Applying the knowledge of this chapter to patient care can help to avoid unnecessary harm to patients and also prevent psychological harm to the anesthesia professional (as the "second victim"). Hence, this chapter is not only about patient safety, but also about the anesthesia professional's safety and well-being as care provider. The authors provide a set of practical safety concepts and strategies to guide the reader in improving or refreshing case management-related skills and to sensitize the reader to safety-related core issues and competencies in anesthesia.

Because most of the work on human performance has focused on anesthesiology in the operating room (OR), this chapter deals primarily with aspects of performance and safety in that setting. Nevertheless, most of the same principles and issues are relevant to other perioperative settings, to critical care, and to a lesser degree, in pain medicine. They will also largely apply to emergency medicine and other health care domains sharing similar cognitive profiles. For readers with a special interest in intensive care, a selection of references is given as a starting point.[1-8]

The chapter contains references ranging from several decades old to quite recent. The authors have tried to balance retention of classic references, where the intellectual content has only changed slightly over the years, with the introduction of current literature that reflects changes in thinking or evidence, or newer syntheses of knowledge and experience.

In this chapter, the authors use "anesthesia professional" to refer to any anesthesia clinician taking care of a patient, whether a physician, certified registered nurse anesthetist (CRNA), or anesthesia assistant (or to similar positions in other countries).

READERS WILL LEARN

- … safety relevant aspects of a dynamic and complex work environment and the resulting consequences for clinicians. Several sections highlight the nature of anesthesia as a highly complex and dynamic working environment and the difficulties that arise for human performance and patient safety.
- … characteristics and risks of different tasks performed by anesthesia professionals and countermeasures to mitigate their potential risks.
- … the issues of human performance, human limitations, and various relevant safety strategies that address them for both individuals and teams.
- … aspects of system safety concerning high-reliability organizations (HROs).

WHAT THIS CHAPTER IS NOT ABOUT

The literature related to human performance and patient safety is vast. Standard reference works are available[9-14] as well as several Internet sources (Appendix 6.1). This chapter samples only a portion of this literature as it most closely relates to the work of anesthesia professionals. This chapter does not address in detail human-machine interactions and the physical design of the work environment. These aspects of human factors, or ergonomics, in anesthesiology are important in their own right. The reader is referred to several publications that review these issues in detail.[15-20] Also not part of this chapter are most issues of infection control and medication safety, even as they pertain to the perioperative arena. Here, too, the reader is referred to several publications that review these issues in detail[21-36] and also to other chapters in this book.

Human Performance and Patient Safety in Anesthesia: Why is this Important?

Even though provision of anesthesia has become a "safe" discipline over the last decades through many scientific and technical improvements, anesthesia per se is an intrinsically hazardous undertaking. Many aspects of anesthetic drugs and care can affect vital human functions and are potentially lethal while they are not therapeutic in themselves. Evolution did not intend for human beings to be rendered temporarily insensitive to pain, unconscious, amnestic, and in many cases paralyzed. The surgical procedure itself may cause or trigger a variety of physiologic derangements and some patients needing anesthesia are already severely ill. Thus, in anesthesiology a stable situation can turn into a life-threatening situation in seconds, minutes, or hours, whereas in many arenas of health care changes happen in days, months, or years.

Medical and technical skills alone are not sufficient for excellent medical care. Historically, an adequately trained anesthesia professional was automatically assumed to always perform appropriately. Deviations from optimal outcomes were understood to result from imperfections in the art and science of anesthesiology. This perception led to heavy emphasis on the scientific and technical aspects of anesthesia training and care. Adverse outcomes were mostly ascribed to unavoidable side effects of a medication, underlying patient disease, negligence, or incompetence on the part of the anesthesia professional.

Interestingly, research shows that the etiology of most adverse events is generally not related to intrinsic problems associated with equipment, drugs, or diseases, but rather that 80% of the avoidable events are caused by so-called human factors (HF)—similar to the statistics emanating from the aviation industry. For instance, a review of critical anesthesia incidents by Cooper and associates revealed that human factors were contributory in 82% of the 359 incidents reported.[37] These incidents ranged from simple equipment malfunction in some cases, to death in others, indicating the seriousness and importance of the problems. Data from an earlier evaluation of 2000 incident reports support these findings with 83% of incidents occurring due to human error.[38] The term HF describes the physical and psychological behavior of humans in relation to specific environments, jobs, organizational patterns, machines, products, and individual challenges.

The performance of human beings is incredibly flexible, powerful, and robust in some aspects but limited and vulnerable in others. Today we have a more complete understanding of the human performance of anesthesia professionals than existed decades ago. For example, we know that the successful conduct of an anesthetic depends on having the requisite technical skills and relevant pathophysiologic knowledge. But it has also become clear that the effective real-time implementation of such expertise to a large extent depends on several nonmedical and nontechnical elements of performance. Among HF issues are those that are termed human performance-shaping factors like fatigue, boredom, and distraction.

Human factor-related safety strategies for the individual and the team are indispensable. Lapses, mistakes, and errors have the potential to harm a patient ("first victim"), but can also harm professionals themselves ("second victim"). Professionals suffer as second victims largely from the perceived guilt about an error that led to actual harm.[39] The clinical institution involved may also suffer financially or in reputation from such events, although often the occurrence of these events are not known to the public, and unlike in other industries (e.g., aviation, chemical manufacturing) there is no direct harm to the physical means of production. Nonetheless, the best way to avoid harm to the professional or the organization is to prevent adverse events or mitigate harm to patients.

Organizational safety attitudes are essential to support high individual human performance. More attention should be devoted to training anesthesia professionals in human performance issues so that they can develop and apply core competencies for achieving human performance on a daily basis. Moreover, departmental and organizational leadership must understand the enormous impact their attitudes and behavior have in shaping human performance, safety culture, outcomes, and ultimately (in all likelihood), the level of patient safety.

Even in anesthesiology, still a long way to go. Historically, anesthesiology was the first medical specialty to specifically focus on the promotion of patient safety. As a consequence, anesthesiology is widely recognized as the pioneering leader in patient safety efforts. Compared to other medical disciplines, the track record of anesthesiology is indeed a model of patient safety for the rest of health care.[40] However, safety science teaches us that patient safety and quality improvement are never-ending processes and complacency is dangerous. In addition, the increasing "production pressure" in anesthesia practice from expanding clinical demands in the face of constant or diminishing resources may threaten previously won gains. Any patient harmed by an anesthetic is one patient too many. This approach is aligned with the zero vision statement of the U.S. Anesthesia Patient Safety Foundation (APSF): *"That no one shall be harmed by anesthesia care."* In this regard Cooper and Gaba wrote that anesthesia professionals "… should remain aware of the hazards they still face, take pride in having been the leaders in patient safety efforts, and stay motivated to continue the pursuit of 'no harm from anesthesia' with the passion it still demands" (p. 1336).[40]

Saving hearts, brains, and lives. Several recently published studies demonstrate the benefits of implementing various patient safety strategies.[5,41-44] The authors have experienced the benefit of a more safety- and human performance-focused approach in their own work, as have their colleagues who also work in this field or in other fields that are endeavoring to create a safer health care system. Although it may be challenging to produce undisputable evidence that patient outcomes are improved by addressing the issues and implementing the strategies presented in this chapter, there is strong reason and ongoing research to support the belief that hearts, brains, and lives have indeed been saved by applying them. That belief is reward enough for the efforts of the authors as they share with the reader what is known about human performance and patient safety.

Nature of the Anesthesia Professional's Operational Domain: A Dynamic and Complex Environment

The practice of anesthesiology can be characterized as a dynamic and complex environment that presents the anesthesia professional with challenges that may jeopardize human performance and patient safety.

To better understand these patient safety challenges that are related to human performance, the authors first describe the key characteristics of anesthesia work. In what follows they address (1) critical factors that categorize anesthesiology as a complex and dynamic working environment; (2) the safety challenge of inherent asymmetry between safety and production, and the effects of production pressure; and (3) the safety challenge of complexity and tight coupling in the anesthesia domain.

ANESTHESIOLOGY BY ITS NATURE INVOLVES CRISES

What makes anesthesiology and a few other medical domains (such as intensive care medicine, emergency medicine, obstetrics, neonatology, and surgery, to name a few) different from most other medical fields? The answer is that the clinical environment of anesthesiology is both complex and dynamic which, when combined with the inherent risks of surgery and anesthesia, makes crisis situations frequent and challenging to deal with. These moments of terror necessitate that anesthesia professionals be expert in crisis management.

CRITERIA DEFINING A COMPLEX AND DYNAMIC WORLD

Based on the work of Orasanu and colleagues,[45] the following text describes some of the characteristics of anesthesia that make it a complex and dynamic world.

1. **Ill-structured problems.** In contrast to well-structured problems, the nature and the goal of ill-structured problems are often vague or unclear, and many problem elements remain unknown or ambiguous. In anesthesiology, the patient's physiologic behavior is not an independent random variable but is causally linked to previous decisions and actions. There often is not just a single problem with a single decision to be made, but rather a variety of interrelated problems. Interdependent decisions must be made and actions taken by the anesthesia professional, surgeon, and other perioperative personnel.
2. **Uncertain system.** The patient is the main "system" of immediate interest to the anesthesia professional, just as the aircraft is of immediate interest to the pilot.[46] Patients are intrinsically very complex, and they contain many components with underlying functions that are imperfectly understood. The medical world knows very little about the underlying causes of specific physiologic events, although the general principles involved can be described. Unlike industrial or aviation systems, patients are not designed, built, or tested by humans, nor do they come with an operator's manual. The true state of the patient cannot usually be measured directly. It must be inferred from ambiguous patterns of clinical observations and data from electronic monitors. These data are imperfect because, unlike industrial systems that are designed and built with sensors in key areas to measure the most important variables, patients are typically instrumented to measure the variables that are easiest to monitor, predominantly with the use of noninvasive methods. Most physiologic functions are observed indirectly through weak signals available at the body surface that are prone to various types of electrical and mechanical interference. Invasive measurements are also vulnerable to artifacts and uncertainties of interpretation. Even if the anesthesia professional knew the exact state of the patient, the patient's response to interventions would be unpredictable, as normal patients show genetic or acquired differences in reflex sensitivity, pharmacokinetics, or pharmacodynamics that can yield a wide range of responses to a given dose of a drug or to a routine action (e.g., laryngoscopy). In diseased or traumatized patients, or in the presence of acute abnormalities, these responses may be markedly abnormal, and patients may overreact or underreact to otherwise appropriate actions. Thus, the patient as a system has substantially greater uncertainty than do engineered systems.
3. **Dynamic environment.** Dynamism stems from the frequency of routine and anomalous changes or events, the rapidity with which they evolve, and the unpredictability of the patient's physiology and response to interventions. An anesthetized patient is in a constant state of change during surgery, with many events outside the anesthesia professional's control, such as when the surgeon inadvertently transects a major vessel or when a patient with a previously unknown allergy suffers anaphylaxis. Although preventive measures can reduce the likelihood of some events, other events cannot be totally avoided because they are inevitable side effects of medically necessary procedures (e.g., surgical blood loss). Unpredictable and dynamic occurrences compete with the preplanned aspects of the case and together they drive the anesthesia professional's actions.
4. **Time stress.** Because the OR is a scarce resource, an incessant overall time pressure exists to use the OR efficiently (see section "Production Pressure"). Surgeons or OR managers pressing to start a case may affect the anesthesia professional's decisions and actions that could jeopardize safety standards. Over the long run this can cause a systematic "normalization of deviance" [47-50] (see section "Normalization of Deviance and Flirting with the Margin"), meaning the emergence of new, less stringent standard behaviors that are seen as normal judgments that previously would have been viewed as aberrant. An even more intense time stress occurs within a case when dynamic situations evolve rapidly and become time critical.
5. **Shifting, ill-defined, or competing goals.** Multiple goals of case management may compete with each other. (e.g., hemodynamic stability vs. good operating conditions for the surgeon vs. rapid emergence from anesthesia). The OR manager's administrative goals (high throughput, low cost) may sometimes compete with those of the anesthesia professional. All these goals shift as the patient's situation changes dynamically throughout a procedure and the flow of cases changes throughout the work day. For example, decisions on surgical operation planning are heavily influenced and manipulated by micropolitics and power, as investigated by Engelmann and colleagues.[51] Nurok and colleagues[52] portray this aspect in their survey: *"Are surgeons and anesthesiologists lying to each other or gaming the system?"*
6. **Short action feedback loops.** The time constants of actions and their effects are very short, on the order of seconds to minutes. Complete intermixing of decision making and action occurs; these functions are not performed in separate cycles. Most decisions and actions are implemented incrementally, constantly evaluating the relative success or failure of actions-to-date to determine how best to proceed. Anesthesia professionals often do not jump to conclusions or implement a whole set of actions all at once but try one or two approaches and see how they work, constantly reassessing rather than jumping ahead too far at once.
7. **High stakes.** The decisions and actions taken by anesthesia professionals can determine the outcome for the patient. The stakes are high because even for elective surgery in healthy patients, the risk of catastrophe is ever-present. Death, brain damage, or other permanent injury may be the end result of many pathways that can begin with seemingly innocuous triggering events. Each intervention, even if appropriate, is associated with side effects, some of which are themselves serious. Some risks cannot be anticipated or avoided. Unlike an event such as a commercial flight, which can be delayed or aborted if a problem occurs or if the weather is bad, these options are not always possible in health care. Sometimes immediate surgery (and anesthesia) may be necessary to treat

a medical problem that is itself life threatening. Balancing the risks of anesthesia and surgery against the risk of the patient's underlying diseases can be extremely difficult.

8. **Multiple players.** Perioperative domains involve multiple players from different professional backgrounds. Each profession has its own characteristics. On the one hand, surgeons, anesthesia professionals and OR nurses all want safety and a good outcome for the patient. On the other hand, each discipline and profession has other inherent goals. For example, surgeons may usually seem eager to perform the surgery and may seem to be more willing to take risks and to view the probability of a good outcome with optimism. In contrast, anesthesiologists may tend to be rather risk averse. Also, for a variety of reasons, it seems that surgeons tend to put production pressure on anesthesia professionals and nurses more than the other way around. The idiosyncrasies of interaction among various individual OR team members sometimes dominate the work environment. The OR sometimes offers a unique team structure of action teams, where the members may vary greatly from one day to the next (see later section "Teamwork"). Furthermore, there is a certain individual variation in the performance of each member; on any given day even usually "good" people may not be at their best.
9. **Organizational goals and norms.** The anesthesia professional works within the formal and informal norms of the OR suite, the anesthesia department, the institution, and the professional culture as a whole. Sometimes anesthesia professionals feel pressured to make decisions that they do not believe are best for the patient in order to comply with these norms. Therefore, it is important to face human performance and patient safety pitfalls not only on the individual and team level, but also on a larger departmental and organizational level (see later section "Patient Safety on the Organizational Level: Issues and Strategies").

Although some of these aforementioned characteristics apply to other domains of medicine, anesthesiology is unique in that many of the characteristics are prominent. In particular, what sets anesthesia apart from clinic-based or ward-based medicine is the intensity of the dynamics, time pressure, uncertainty, and extreme variation within the complexity, with danger lurking just below the surface, as well as the unique team constellation of so-called action teams (see section "Human Factors on the Team Level").

Other factors influencing complexity in anesthesia: device variety and tight coupling. The complexity in anesthesia also stems from the variety of devices in use and their interconnections. The challenge is that the equipment often consists of a proliferation of independent devices with multiple, nonstandardized interconnections. Devices seem often to be designed by engineers in isolation. As a consequence, interactions between devices, or among the equipment, the patient, and the human operator, may not be adequately addressed in the design phase.

Furthermore, complexity in anesthesia derives from complex interactions which are highly interdependent (tightly coupled). Coupling describes the notion of relations between parts of a system, which either can be tightly or loosely coupled.[46] Because many body systems affect each other, the patient is a major site of tight coupling. The anesthetic state tends to erode the protective and compensatory physiologic buffers among some of these interconnected systems, thereby forcing the patient's system to become even more connected and strengthening the coupling between them and between the patient and external technologic supports (e.g., ventilator or infusions of hemodynamically active drugs).

PRODUCTION PRESSURE RESULTING IN ASYMMETRY BETWEEN SAFETY AND PRODUCTION

The current trend of increasing production pressure in perioperative care can further strain the working conditions in this demanding work environment.[53] Social and organizational environments may act as a source of production pressure on anesthesia professionals.

Safety attitudes compete against economic thinking. Production pressure encompasses the economic and social pressures placed on workers to consider production, not safety, their primary priority.[54] In anesthesiology, this typically means starting cases early, keeping the OR schedule moving speedily, with few cancellations and minimum time between cases. In principle, safety and efficiency can go hand in hand. Many aspects of high reliability, such as standard operating procedures, preprocedure briefings, and flattening the hierarchy, may smooth operation of the system, as well as make it safer. However, the pressure for throughput as well as the wish to please the surgeon or the OR manager, or the attempt to make up time by skipping essential procedures can erode safety and lead to a normalization of deviance (the new normal, see sections "Normalization of Deviance" and & "Flirting with the Margin").[55] For example, when anesthesia professionals succumb to production pressures, they may skip appropriate preoperative evaluation and planning, or they may not perform adequate pre-use checkout of equipment. Even when preoperative evaluation does take place, overt or covert pressure from surgeons (or others) can cause anesthesia professionals to proceed with elective cases despite the existence of serious or uncontrolled medical problems.

Production pressure as a trigger to depart inappropriately from standard operating procedures and standards. Production pressure can cause anesthesia professionals to choose techniques that they would otherwise believe to be inadvisable. Gaba and associates reported on a survey of a large random sample of California anesthesiologists concerning their experience with production pressure.[56] A nontrivial minority of respondents (20% to 40%) reported meaningful levels of pressure to conform to such pressures, to make decisions against their judgment of optimal safety, and to risk economic consequences if they act as they see appropriate. Generally, the pressures were already internalized after prior unpleasant experiences rather than stemming from blatant external attacks. Although there are anecdotal reports of increasing production pressure, as well as organizational practices that increase it (e.g., scheduling elective cases to start late at night or after midnight without separate shifts of anesthesia professionals), there has been no comparable repeated survey of such pressures in recent years. Fully investigating these aspects of the work environment is difficult because such relationships are driven by economic considerations, as well as by the complex organizational and interpersonal networks linking the different medical cultures. Changing the environment will be equally challenging and calls for organizational action (see section "Patient Safety Strategies on the Individual and Team Level: Crisis Resource Management [CRM] and Other Training Curricula").[57]

The efficiency-thoroughness trade-off (ETTO). Given the limited resources in the health care system, professionals constantly need to prioritize and make trade-offs, the most common being the efficiency-thoroughness trade-off (ETTO) described in detail by Eric Hollnagel in his book *The ETTO Principle: Efficiency-Thoroughness Trade-Off: Why Things that Go Right Sometimes Go Wrong.*[58] One example of a tradeoff is reducing the amount of information sought about individual preoperative patients in order to more efficiently process large numbers of them. Since it rarely is possible to be both effective and thorough at the same time, the balance of the trade-off can get into an unnoticed disequilibrium threatening human performance and patient safety.

Inherent imbalance between signals of safety and signals of production. One of the challenges in achieving optimal safety is the asymmetry of the signals of safety and the signals of production[59]: (1) Investments for production are easy to plan for and measure. Feedback about production is easy to obtain (revenue, earnings, expenses) and to interpret (success, no success). Success is indicated positively (more production, more earnings) and reinforcing. The relationship between the application of resources (money, effort, time) and production goals is relatively certain. (2) On the contrary, investments for safety are more difficult to plan for and the costs and benefits can only be measured indirectly and without continuity, making them difficult to interpret or even deceptive. Feedback about safety is inherently weak and ambiguous. Success is less reinforcing because if indicated negatively (fewer accidents or incidents)—how can one measure the accidents that could have occurred but did not? The relationship between the application of resources (money, effort, time) and safety goals is equally uncertain. There have been many occasions when only after a catastrophe takes place are the signals concerning a safety hazard understood, and often there is evidence that some personnel did recognize the hazards but either did not sufficiently press the issue or else they were systematically ignored or repressed.

Nature of the Anesthesia Professional's Work: Task Variation and Workload Management

As previously described, the operational domain of anesthesia can be considered as a complex and dynamic world, managing different challenges with uncertain systems, competing goals, time pressure, and multiple players with special team constellations. All of these can affect human performance and patient safety. There also exist the challenges of the different specific tasks of conducting an anesthetic, whether manual (i.e., insertion of cannula, intubation), behavioral (i.e., leadership behaviors, communication patterns), or cognitive (i.e., attention, preparedness, dynamic decision making). Safe and efficient performance requires both medical and non-medical skills.[11,60]

Human failure or equipment failure can have disastrous consequences. Errors in cognitive tasks as well as cognitive biases are common in anesthesiology and pose a threat to patient safety.[61,62] In the following section the authors provide insights into the nature of the anesthesiaology professional's many tasks and their various vulnerabilities. This is important not only for individual and team improvements but also for improvements concerning clinical education, training, organizational structures, and equipment design. The focus of the upcoming section is on manual and cognitive tasks. The behavioral non-medical are discussed later (see section "Patient Safety on the Individal and Team Level").

This section briefly highlights the different phases of an anesthetic regimen and summarizes findings of task analysis and task performance studies, provides facts about the anesthesia machine checkout protocol as a safety relevant task, and introduces nonobservable cognitive tasks of administering anesthesia, in particular dynamic decision making. In addition, this section provides an introduction to workload measurement methodologies, gives study results concerning the performance of anesthesia professionals summarizes the benefits and obstacles of human performance measures, and highlights results from task analysis studies.

PROCEDURAL TASKS OF ANESTHESIA PROFESSIONALS AND RELATED VULNERABILITIES

Multiple task analysis studies have investigated what actions and thought processes an anesthesiologist is required to perform to achieve good anesthetic care. Since the 1970s, numerous studies have been done either by direct observation during real cases[63-67] or by indirect observation during cases captured on videotape.[64,68-74] In addition, an increasing number of studies have been performed in realistic simulation environments.[8,64,75-79] Of note, many of the studies cited are pioneering ones that remain valid today.

The early studies of the work of anesthesiologists drew attention to the wide spectrum of tasks in the trajectory of perioperative care. They highlighted that many tasks must be done in close parallel with others (approximating multitasking, see section Task Management), showing not only the different tasks and their substeps that can be prone to error, but also different phases of task intensity during an anesthetic. Subsequent task analysis studies focused on the workload and the performance of the anesthesiologist, at a later time expanding to performance measures based on teamwork,[80-82] communication,[83] and leadership.[82,84,85] More recently, task analysis studies have been performed with respect to ergonomic equipment design questions. Certain very complex issues concerning human-machine interactions and the ways in which technology affects behavior in complex patient-care environments are beyond the scope of this chapter; however a number of publications address these issues.[16,86,87]

The different phases for an anesthetic regimen are commonly classified into (1) preoperative planning, (2) induction, (3) maintenance of, and (4) emergence from anesthesia. [63] Every phase is characterized by manual and cognitive tasks, each of which consists of further subordinated steps and each of which presents with a variable density of tasks and human error pitfalls. For a comprehensive review, the reader is directed to the publication of Phipps and colleagues [63] for detailed information.

Preoperative Planning

The anesthesia professional needs to be prepared for active intervention during the whole anesthetic regimen. Part of this preparedness involves obtaining the necessary equipment and supplies, preparing medications, and conducting pre-use checkouts of life-support equipment and the anesthesia machine before induction (See section "Pre-use Checkout of Equipment/Anesthesia Machine Checkout").

However, with 44 task steps as identified in the task analysis study by Phipps and associates, the equipment check is a lengthy and detailed process, and it is possible that steps may be omitted, either intentionally or unintentionally.

Induction

Task analysis studies demonstrated increased anesthesiologist workload during induction, emergence, and emergency surgery.[63,67,88-94] Phipps and associates identified 73 task steps between the preparation of drugs and transferring the anesthetized patient to the operating room (induction phase), including cognitive and communicative tasks, machine checkouts, as well as a considerable number of manual task steps, such as the insertion of the cannula and airway devices. Pape and Dingman examined the number of unrelated distractions during the induction process (i.e., unrelated questions of other personnel, OR doors opening and closing, noise, answering incoming telephone calls, unrelated communication), discovering an average of 7.5 total interruptions per 9 minutes.[95] They argued that interruptions and distractions can lead to loss of focus and result in errors, and requested further research to determine whether silence during induction is needed as a safety measure. Another study concluded that on average during cases one distractive event occurs every 4 minutes 23 seconds, with approximately 3.4 distractions during induction and 3.0 distractions when moving from the induction room to the OR.[96] In this study while most distracting events had no negative consequences for the patient, 22% had negative consequences (suboptimal management). Interestingly 3% were actually not distractions because they had positive consequences for the patient. In another study, 20% of visual attention during induction was directed to the patient monitor, increasing up to 30% during simulated critical incident induction scenarios.[97] During the observation of real cases, yet another study group found that drug/fluid tasks comprised 20 ± 6% of induction, 15 ± 8% of maintenance, and 12 ± 7% of emergence during routine cases.[91]

Maintenance Phase of Anesthesia

Betza and colleagues found in an observational study that anesthesia providers spent 71% of their time during maintenance doing patient or display monitoring tasks.[98] Transitions between the task categories occurred approximately once every 9 seconds. It appeared that regardless of the task, there was a high frequency of task transitions to look at the visual displays and then from the visual displays toward the patient. Compared with the induction phase, there are fewer (16) task steps during the maintenance phase. [63] However, there is evidence that a relatively high proportion of critical incidents occur during the maintenance phase (59% of incidents during maintenance, 26% during induction).[37] Patients' conditions may vary in an overt or subtle way. Therefore, anesthesia professionals need to continuously monitor several parameters. Their attention may be distracted or misbalanced, as not all parameters need the same level of attention all the time. Sometimes other tasks, such as telephone calls, auscultation, insertion of an arterial cannula, use of transesophageal echocardiography (TEE), and "problem solving," may divert the attention of the anesthesia professional. As attention is a limited resource and susceptible to distractions, it is important to learn how to best allocate one's attention in continuously changing and complex environments like anesthesia (see later section, "Situation Awareness").

Very detailed task analyses took place in a series of studies carried out by the University of California, San Diego (UCSD), Stanford University, the San Diego and Stanford Veterans Administration Medical Centers.[66,67] Generally, studies of workload indicate that induction and, to a lesser degree, emergence are the most intensive. However, it is also argued that many of those tasks performed are part of a routine, which tends to reduce the effort required. Maintenance, in contrast, is typically less physically "action dense" but mental activity continues as a wide range of information is used and processed.[99]

Emergence

With 40 task steps to carry out in a relatively short period of time, the discontinuation of anesthesia and subsequent transfer of the patient to recovery is fairly busy.[63] A study from Broom and associates suggests that emergence is the most distractive period compared with induction and maintenance, finding noise during emergence at 58 decibels (dB) (compared to induction at 46 dB and maintenance at 52 dB), with sudden loud noise (>70 dB) occurring more frequently during emergence than at induction or maintenance.[100] The range of staff entrances and exits were also highest during emergence (10), compared to induction (0) and maintenance (6). Conversations unrelated to the procedure occurred in 93% of emergences. Emergence also was found to be the period of most frequent distractions, occurring on average every 2 minutes.[96] Those findings are acknowledged by the following quotations retrieved from subjective study interviews:

> *"I don't think people quite appreciate that emergence is as important as induction really and sometimes they're just glad to have finished off their case. They're crashing and banging and moving on and fail to realize." and "(…) [B]asically as far as they're concerned the job's finished. They're there moaning, yelling, or talking about the next case. I do find that distracting because I think: 'we haven't actually finished this case yet'." (p. 711)*[96]

PATIENT SAFETY ACTION BOX

The period of the patient's emergence from anesthesia is high risk and a high workload for the anesthesia professional while low stress for other OR personnel. Often they forget and the noise level may rise considerably. If so the anesthesia professional should politely demand thoughtfulness and quiet from the other OR team members. This would also be a possible setting to invoke the auditory "sterile cockpit" protocol (see later section "Distractions and Interruptions in the Operating Room").

PRE-USE CHECKOUT OF EQUIPMENT/ ANESTHESIA MACHINE CHECKOUT

A pre-use check to ensure the correct functioning of anesthetic equipment is essential to patient safety. Failure to check anesthesia equipment prior to use can lead to patient injury or "near misses."[101,102] Based on a retrospective incident analysis of 668 reported incidents, Marcus reported a total of nearly 18% of in-theater incidents in pediatric anesthesia resulted from the failure to check.[102] More recent generations of anesthesia machines have internal computers that can conduct checks of many aspects of machine functioning and alert the anesthesia professional to problems. However, the authors have observed in simulations of embedded machine problems or external equipment faults (e.g., nitrous oxide vs. oxygen swap) that anesthesia professionals may lack a complete understanding of these systems.

In the United States an updated machine checklist was released by the American Society of Anesthesiologists (ASA) in 2008.[103] Because no specific checkout recommendation could be applicable to all modern anesthesia delivery systems and to all anesthetizing locations, the latest recommendation is based on a set of design guidelines for the pre-anesthetic checkout and provides samples of checkout procedures (available at: www.asahq.org/resources/clinical-information/2008-asa-recommendations-for-pre-anesthesia-checkout). The 2008 pre-use anesthesia apparatus checkout recommendation (AACR) contains a list of 15 separate items that should be checked at the beginning of each day (preoperative check) or whenever a machine is moved, serviced, or the vaporizers changed. Eight of these items should be checked prior to each procedure (preinduction check). Some of the steps may be already part of an automated manufacturer's checkout process in the anesthesia machine; others need to be performed individually. Feldman and associates state:

> *"Following these checklists will typically require <5 minutes at the beginning of the day, and <2 minutes between cases, but will provide you with the confidence that the machine will be able to provide all essential life support functions before you begin a case." (p. 6)*[104]

In 2012, the Association of Anaesthetists of Great Britain and Ireland (AAGBI) released a new safety guideline on checking anesthesia equipment that also includes, but is not limited to, the pre-use checkout of the anesthetic machine (available at: https://www.aagbi.org/sites/default/files/checking_anaesthetic_equipment_2012.pdf).[105] Rather recently revised guidelines on pre-use checking of the anesthetic equipment including the anesthesia workstation have been published by the Australian and New Zealand College of Anaesthetists (ANZCA)[106] in 2014 and by the Canadian Anesthesiologists' Society (CAS)[107] in 2016.

PATIENT SAFETY ACTION BOX

There are numerous checkout checklists available. A serious patient safety issue is the non-adherence to standard protocols. The anesthetic checkout of equipment is a method of systematically ensuring the anesthetic professional executes a thorough check of the anesthetic equipment. All professionals should therefore use it as a standard practice for checking the anesthetic machine to provide the best and safest patient care. The implementation of a checklist is an organizational process that needs systematic implementation and, optimally, user training.

COGNITIVE TASKS OF ADMINISTERING ANESTHESIA AND RELATED VULNERABILITIES

The observable tasks do not tell the whole story of what the anesthesia professional is doing. Even when the anesthesia professional appears idle, most of the time mental activity is ongoing. Several investigators have written about the cognitive elements in anesthesiology.[91,108-111] Of those errors made, cognitive errors and cognitive biases in anesthesiology are common and pose a threat to patient safety.[61,62,102] In the following section, (1) the cognitive tasks of dynamic decision making and situation awareness are described and summarized in the anesthesia professional's core cognitive process model; (2) subsequently, the management and coordination of the core cognitive process model are discussed in this section; and (3) several methodologies to measure cognitive workload are touched on.

Introduction of the Anesthesia Professional's Core Cognitive Process Model

Besides the constant check whether anticipated milestones of the anesthetic regimen are achieved and the constant check of incoming data streams, the anesthesia professional must also react to a large number of contingencies, some of which can be predicted in advance based on the patient's history and the type of surgery, whereas others cannot. If so, the existing plan may have to be reactively modified.

Different aspects of decision making and situation awareness are summarized in the anesthesia professional's core cognitive process model. The model was developed by David Gaba and draws heavily on the work of a number of other investigators who studied human performance in a variety of complex, dynamic worlds.[91,112-114] It is described in detail as a framework for understanding the empiric data, and provides a vocabulary for discussing the elements of both successful and unsuccessful performance by anesthesia professionals.

The entire core process model, shown in Fig. 6.1, depicts the anesthesia professional as working at five different interacting cognitive levels (resource management level,

Fig. 6.1 Core cognitive process model of the anesthetist's complex real-time problem-solving behavior (see text for detailed description). Five levels of cognition operate in parallel. The core process involves a main loop (solid arrows) of observation, decision, action, and reevaluation. The core process is managed by two levels of metacognition that involve a second, higher-level loop (both above the core process): supervisor control (allocation of attention) and resource management. Each component of the model requires different cognitive skills. Each component is vulnerable to a different set of performance failures or errors. *BP*, Blood pressure; *CO*, cardiac output; *MAP*, mean arterial pressure; *SVR*, systematic vascular resistance. procedural level, communication level, abstract reasoning level, supervisory control level) to implement and control a core process of observation, verification, problem recognition, prediction of future states, decision making, action, and reevaluation (Box 6.1). The core process must then be integrated with the behavior of other team members and with the constraints of the work environment. Expert performance in anesthesia involves these features in a repeated loop of the different steps. Errors can occur at each step in this process.

The division of mental activities into levels follows the work of Rasmussen and Reason et al..[113,115] Having multiple levels supports the concepts of parallel processing (performing more than one task at a time but working on different levels of mental activity) and multitasking/multiplexing (performing only one task at a time but switching very rapidly from one task to another), as shown in several task analysis studies.[64,67,89] Table 6.1 gives an overview and a brief explanation of the different mental activity levels.

At the sensorimotor level, activities involving sensory perception or motor actions take place with minimal conscious control; they are smooth, practiced, and highly integrated patterns of behavior. At the procedural level, the anesthesia professional performs regular routines in a familiar work situation. These routines have been derived and internalized from training and from previous work episodes. A level of abstract reasoning is used during preoperative planning, and intraoperatively it is used in unfamiliar situations for which no well-practiced expertise or routine is available from previous encounters. Rasmussen's model[113] was extended by the explicit addition of two additional levels of mental activity—the supervisory and the resource management level—that provide for dynamic adaptation of the anesthesia professional's own thought processes. Supervisory control is concerned with dynamically allocating finite

TABLE 6.1 Levels of Mental Activity

Level of Control	Explanation	Comments
Resource management level	Command and control of all resources, including teamwork and communication	Incident analysis shows a huge contribution of lack of resource management and communication skills to the development of incidents and accidents; the importance of these factors is reflected in the ACRM principles and simulation training courses (see Chapter 7)
Supervisory control level	Metacognition: thinking about thinking	Dynamic adaptation of the thought process, decision making (e.g., avoiding fixation errors), scheduling, and remembering actions (e.g., prospective memory tasks)
Abstract reasoning level	Use of fundamental medical knowledge, search for high-level analogies, deductive reasoning	Often in parallel with other levels; in emergency situations often too slow and too sensitive to distractions in high-workload situations
Procedural level	Precompiled responses, following algorithms, heuristics, "reflexes"	Recognition-primed decision making—experts are more often on this level; special errors may occur as a result of not checking for the appropriateness of the "procedure"; less experienced personnel may misuse this level for ill-considered, unadapted "cookbook medicine"
Sensorimotor level	Use of all senses and manual actions; "feeling, doing, hearing"; sometimes subconscious control of actions	Experts perform smooth action sequences and control their actions by direct feedback from their senses (e.g., action sequences of placing an intravenous line or endotracheal intubation; skill-based errors such as slips and lapses may occur)

ACRM, Anesthesia crisis resource management.

attention between routine and non-routine actions, among multiple problems or themes, and among the five cognitive levels. Attention is such a scarce resource, therefore its allocation is extremely important in every aspect of dynamic decision making. Resource management deals with the command and control of available resources, including teamwork and communication. Expert performance in anesthesia involves these features in a repeated loop. An overview of the core cognitive process and its elements is given in Box 6.1. The elements are explained in detail in the following text sections and include (1) observation; (2) verification; (3) problem recognition; (4) prediction of future states; (5) precompiled responses; (6) action taking/action implementation; and (7) reevaluation.

Observation. Anesthesia professionals use observations to decide whether the patient's course is on track or whether a problem is occurring; this is the first step of the decision making cycle. Data are observed and transformed by interpretation into information, followed by further interpretation into meaning. Data streams typically involve direct visual, auditory, or tactile contact with the patient, the surgical field, routine electronic monitoring, special (sometimes invasive) monitoring systems, contents of suction canisters and sponges, reading of reports of laboratory test results, and communications from other personnel. Loeb showed that anesthesiologists typically observe monitors for approximately 1 to 2 seconds every 10 to 20 seconds and that it usually took several observing cycles before they detected a subtle cue on the monitor.[88] Management of rapidly changing situations requires the anesthesia professional to assess a wide variety of information sources. Because the human mind can attend closely to only one or two items at a time, the anesthesia professional's supervisory control level must decide what information to attend to and how frequently to observe it (as later shown at CRM key point 14 "Allocate attention wisely"). Constant observation and interpretation of the different information systems is executed repeatedly throughout the course of an anesthetic regimen. The plethora of simultaneous data streams in even the most routine cases is a challenge. Vigilance, defined as the capacity to *sustain* attention, plays a crucial role in the observation and detection of problems and is a necessary prerequisite for meaningful care. Vigilance can be degraded by performance-shaping factors (see later section "Performance Shaping Factors") and it can be overwhelmed by the sheer amount of information and the rapidity with which it is changing.

Verification. In the working environment of an anesthesia professional, the available, observed information is not always reliable. Most monitoring is noninvasive and indirect and is susceptible to *artifacts* (false data). Even direct clinical observations such as vision or auscultation can be ambiguous. Brief *transients* (true data of short duration) can occur that quickly correct themselves. To prevent them from skewing the decision making process and triggering precipitous actions that may have significant side effects, critical observations must be verified before the clinician can act on them. This requires the use of all available data and information and cross-checking different related data streams rather than depending solely on any single datum without sensible interpretation (as later shown in CRM key point 8 "Use all available information" and CRM key point 10 "Cross check and double check; never assume anything"). Verification uses a variety of methods, shown in Table 6.2.

PATIENT SAFETY ACTION BOX

Try to be sensitive to changes and do not just explain them away as normal without double-checking or using other information to determine if everything really is okay. Assume there is a big problem unless you can prove otherwise. If in doubt, it should always be assumed that the patient is at risk and that the parameter in question is real (rule out the worst case). The burden of proof is on you. Beware of too easily assuming that it is just a technical artifact.

TABLE 6.2 Methods for Verification of Critical Observations

Method	Explanation and Example
Repeating	The observation or measurement is repeated to rule out a temporary wrong value (e.g., motion artifacts during noninvasive blood pressure measurement)
Checking trend information	The short-term trend is observed for plausibility of the actual value. Trends of physiologic parameters almost always follow curves, not steps
Observing a redundant channel	An existing redundant channel is checked (e.g., invasive arterial pressure and cuff pressure are redundant, or heart rate from an ECG and pulse oximeter)
Correlating	Multiple related (but not redundant) variables are correlated to determine the plausibility of the parameter in question (e.g., if the ECG monitor shows a flat line and “asystole” but the invasive blood pressure curve shows waves)
Activating a new monitoring device	A new monitoring modality is installed (e.g., placing a pulmonary artery catheter). This also adds another parameter for the method of “correlating”
Recalibrating an instrument or testing its function	The quality and reliability of a measurement are checked, and its function is tested (e.g., if the CO_2 detector shows no values, the anesthetist can exhale through it to see whether the device works). Observation of redundant channels can also help verify a value (see above)
Replacing an instrument	If doubt exists about the function of a device, an entirely new instrument or an alternative backup device may be installed
Asking for help	If the decision on the values remains unclear, help should be sought early to obtain a second opinion from other trained personnel

ECG, Electrocardiogram.

Problem Recognition. Having recognized a problem, how does the expert anesthesia professional respond? The classical paradigm of decision making involves a careful comparison of the evidence with various causal hypotheses that could explain the problem. This is followed by a careful analysis of all possible actions and solutions. This approach, although powerful, is relatively slow and does not work well with ambiguous or scanty evidence. Many perioperative problems faced by anesthesia professionals require quick action under uncertainty[116,117] to prevent a rapid cascade to a catastrophic adverse outcome, and solution of these problems through formal deductive reasoning from first principles is just too slow. The process of problem recognition is a central feature of several theories of cognition in complex, dynamic worlds.[110,118,119] Problem recognition involves matching sets of environmental cues to patterns that are known to represent specific types of problems. Given the high uncertainty seen in anesthesia, the available information sources cannot always disclose the existence of a problem, and even if they do, they may not specify its identity or origin. Anesthesia professionals use approximation strategies to handle these ambiguous situations; psychologists term such strategies *heuristics*.[120] Stiegler and Tung give a detailed review of heuristics and other biases that affect problem recognition.[121] One heuristic is to categorize what is happening as one of several generic problems, each of which encompasses many different underlying conditions (similarity/pattern matching). Another is to gamble on a single diagnosis (frequency gambling[115]) by initially choosing the single most frequent candidate event. During preoperative planning, the anesthesia professional may adjust a mental “index of suspicion” for recognizing certain specific problems anticipated for that particular patient or surgical procedure. The anesthesia professional must also decide whether a single underlying diagnosis explains all the data or whether they could come from multiple causes. This decision is important because excessive attempts to refine the diagnosis can be very costly in terms of allocation of attention. By contrast, a premature diagnosis can lead to inadequate or erroneous treatment. The use of heuristics is typical of expert anesthesia professionals and often results in considerable time savings in dealing with problems. However, it is a double-edged sword. Both frequency gambling and inappropriate allocation of attention solely to expected problems can seriously undermine problem solving when these gambles do not pay off or are not corrected in the reevaluation process.

Many of the issues that are related to problem recognition and cognition in general are discussed in more detail in the section on decision making further below, especially when dealing with the models of System I thinking and System II thinking and of recognition-primed decision making.

Prediction of Future States. Problems must be assessed in terms of their significance for the future states of the patient.[110,118] Predicting future states based on the occurrence of seemingly trivial problems is a major part of the anticipatory behaviors that characterize expert crisis managers. Problems that are already critical or that can be predicted to evolve into critical incidents receive the highest priority (as later shown in CRM key point 15 “Set priorities dynamically”). Prediction of future states also influences action planning by defining the timeframe available for required actions. Cook and colleagues described *“going sour”* incidents in which the future state of the patient was not adequately taken into account when early manifestations of problems were apparent.[122] One of the challenges known from research in psychology is that the human mind is not very well suited to predict future states, when things are changing in a nonlinear fashion. Under such circumstances, which are common for natural systems such as the human body, the rate of change is almost invariably underestimated, and people are surprised at the outcome.[123]

PATIENT SAFETY ACTION BOX

Slow but steady and sustained blood loss in a child during surgery might result in few or subtle changes in hemodynamics for some time until rapid decompensation occurs. If the weak signs of the developing problem were not detected or misjudged the ensuing catastrophe may seem to have occurred suddenly. The use of a visible trend monitoring of heart rate or blood pressure over a longer period of time can help the anesthesia professional to be better aware of changes that are not readily apparent if only the last few measurements are compared.

Precompiled Responses. Once a critical event has been observed and verified the anesthesia professional needs to respond. In complex, dynamic domains, the initial responses of experts to the majority of events stem from *precompiled* rules or response plans for dealing with a recognized event.[115] This method is referred to as recognition-primed decision making,[114,124] because once the event is identified, the response is well known (see later section "Decision Making"). In the anesthesia domain, these responses are usually acquired through personal experience alone, although there is a growing realization that critical response protocols must be codified explicitly and taught systematically. Experienced anesthesia professionals have been observed to rearrange, recompile, and rehearse these responses mentally based on the patient's condition, the surgical procedure, and the problems to be expected.[125] Ideally, precompiled responses to common problems are retrieved appropriately and executed rapidly. When the exact nature of the problem is not apparent, a set of *generic* responses appropriate to the overall situation may be invoked. For example, if a problem with ventilation is detected, the anesthesia professional may switch to manual ventilation at a higher fraction of inspired oxygen (FiO_2) while considering further diagnostic actions. However, experiments involving simulation have demonstrated that even experienced anesthesia professionals show great variability in their use of response procedures to critical situations.[75,125-127] This finding led these investigators to target simulator-based training in the systematic training of responses to critical events.[108,128]

Even the ideal use of precompiled responses is destined to fail when the problem does not have the suspected cause or when it does not respond to the usual actions. Anesthesia cannot be administered purely by precompiled "cookbook" procedures. Abstract reasoning about the problem through the use of fundamental medical knowledge still takes place in parallel with precompiled responses, even when quick action must be taken. This seems to involve a search for high-level analogies[115] or true deductive reasoning using deep medical and technical knowledge and a thorough analysis of all possible solutions. Anesthesia professionals managing simulated crises have linked their precompiled actions to abstract medical concepts.[125]

Taking Action/Action Implementation. Anesthesiologists need to share their attention among different cognitive levels, among tasks, and often among problems. The intensive demands on the anesthesia professional's attention could easily swamp the available mental resources. Therefore, the anesthesia professional must strike a balance between acting quickly on every small perturbation (which requires a lot of attention) and adopting a more conservative "wait-and-see" attitude. This balance must be constantly shifted between these extremes as the situation changes. However, during simulated crisis situations, some practitioners showed great reluctance to switch from business as usual to emergency mode even when serious problems were detected.[75] Erring too far in the direction of wait and see is an error that can be particularly catastrophic. Preparedness for active intervention in case of dynamically changing events is a key element of an anesthesiologist's work. But how frequent is this requirement? According to the review of Wacker and Staender, adverse events in the perioperative period continue to be frequent, occur in about 30% of hospital admissions, and may be preventable in more than 50%.[129]

PATIENT SAFETY ACTION BOX

Once you are sure there is a big problem, it is important for the entire team to transition into emergency mode efficiently. One way of doing so is to declare the emergency out loud with appropriate force, such as: *"Ok, everybody, there's a very serious problem with the patient—probably anaphylaxis—this is a major emergency."*

At any time during an anesthetic regimen there may be multiple things to do, each of which is intrinsically appropriate, yet they cannot all be done at once. Simulation experiments have shown that anesthesia professionals sometimes have difficulty selecting, planning, and scheduling actions optimally.[75]

PATIENT SAFETY ACTION BOX

It helps if team members know the actions planned and the schedule of actions preferred (referred to as shared mental models). If the anesthesia professional does not provide the information, team members should check with the anesthesiologist. It also is helpful to distribute actions with clear communicated priorities and/or timeframes (CRM principle 7: "Effective Communication", e.g., *"[Name of receiver of message], prepare xxx first, then I need xxx, and after that bring me xxx,"* or *"After you have done xxx, let's start xxx together"*, or *"In 30 minutes, please check the blood gases/blood sugar level/ etc. again…"*)

A particular hallmark of anesthesiology is that the decision maker does not just decide what action is required but is often involved directly in the implementation of actions. Executing these actions requires substantial attention and may in fact impair the anesthesia professional's mental and physical ability to perform other activities (e.g., when an action requires a sterile procedure). This is particularly an issue when other tasks have been interrupted or temporarily suspended. *Prospective memory,*[130-134] one's ability to remember in the future to perform an action (i.e., to complete a task) can be easily disrupted. In addition, anesthesia professionals engaged in a manual procedure are strongly constrained from performing other manual tasks or from maintaining awareness of incoming information.

Reevaluation. In order to successfully solve dynamic problems and to cope with the rapid changes and profound diagnostic and therapeutic uncertainties seen during anesthesia, the core process must include repetitive reevaluation of the situation. Thus, the reevaluation step, initiated by the supervisory control level, returns the anesthesia professional to the observation phase, but with specific assessments in mind (see also CRM key point 12, "Reevaluate repeatedly"). Only by frequently reassessing the situation can the anesthesia professional adapt to dynamic processes, since the initial diagnosis and situation assessment can be incorrect. Even actions that are appropriate to the problem are not always successful.

BOX 6.2 Reevaluation Questions—Maintaining Situation Awareness

- Did the actions have any effect (e.g., did the drug reach the patient?)?
- Is the problem getting better, or is it getting worse?
- Are there any side effects resulting from previous actions?
- Are there any other problems or new problems that were missed before?
- Was the initial situation assessment/diagnosis correct?
- What further developments can be expected in the (near) future?

The process of continually updating the assessment of the situation and monitoring the efficacy of chosen actions is termed *situation awareness*.[118,119] Situation awareness is a very interesting and important topic in analyzing performance and reasons for errors[110,135,136] and is discussed in detail in a later section. Box 6.2 gives examples of reevaluation questions in order to maintain situation awareness.

Faulty reevaluation, inadequate adaptation of the plan, or loss of situation awareness can result in a type of human error termed *fixation error*.[137,138] Fixation errors have been described in responses of professionals to abnormal situations.[125,126,137-139] Avoiding and recognizing fixation errors in the field of anesthesia is covered more in detail in section "Introduction of the 15 Crisis Resource Management Key Principles."

Management and Coordination of the Core Cognitive Process: Supervisory Control and Resource Management

Anesthesia professionals' abilities to adapt their own thinking (metacognition—thinking about thinking) through supervisory control and resource management are key components of dynamic decision making and therefore of crisis management.

Supervisory Control. The supervisory control allocates the scarce resource of attention during multitasking, and oversees and modulates the core process. For example, determining the frequency of observation of different data streams, prioritizing diagnostic and therapeutic alternatives, actively managing workload, prioritizing and scheduling actions. Supervisory control actively manages the workload by (1) avoiding high-workload situations by anticipation and planning, (2) distributing workload over time or (3) over personnel, (4) changing the nature of the task to reduce work, or (5) minimizing distraction. More details regarding the active management of workload are touched on in the later section on CRM key point 5 "Distribute the Workload."

Resource Management. The highest layer of metacognition and control is known as resource management—the ability to command and control all the resources at hand to care for the patient and to respond to problems. This involves translating the knowledge of what needs to be done into effective team activity by taking into account the limitations of the complex and often ill-structured perioperative domain. Resources include personnel, equipment, and supplies, both in the immediate vicinity and, when necessary, throughout the various levels of the organization. Resource management explicitly demands teamwork and crew coordination. It is not enough for the anesthesia professional to know what to do or even to be able to do each task alone. Only so much can be accomplished in a given time, and some tasks can be performed only by other skilled personnel (e.g., catheterization lab). A key responsibility of the anesthesia professional is to mobilize needed resources and to distribute the relevant goals and tasks among those available. The details of this critical function are described in the section on "Crisis Resource Management."

ANESTHESIA PROFESSIONAL'S WORKLOAD AND METHODOLOGIES TO MEASURE IT

Most anesthesia professionals have significant other responsibilities in addition to the manual, cognitive, and behavioral duties described above, for example in administration, supervision, or teaching. Depending on the task, the task density, the individual's experience and skill, the patient's state, and the given circumstances (production pressure, staff availability, noise, light, space, team, etc.), the workload of the anesthesia professional can change at any time during an anesthetic regimen. Cognitive resources are diminished when the workload is heavy (i.e., during task dense phases like induction, emergence, or during an emergency), leading to lower levels of performance,[76,127] increased response time, [93] decreased vigilance,[90,92] and greater risk of errors.

The concept of workload is tricky to define. Hart and Staveland[140] describe it as follows: *"Workload is not an inherent property, but rather emerges from the interaction between the requirements of a task, the circumstances under which it is performed, and the skills, behaviors, and perceptions of the operator"* (p. 140). Psychology literature suggests that emotions during highly demanding activities impair cognitive processing efficiency.[141] Task analysis studies as described earlier and task (action) density studies (see later) give insights into several aspects of workload, especially facilitating workload measurements by identifying the individual work components or subtasks to be measured. However, those kind of studies do not necessarily give insight into the performance shaping aspects of workload.

Methods to measure workload include task performance via observation, subjective assessments, and physiological measures. They are described below. For a more comprehensive review, see, for example, Leedal and Smith, [142] and Byrne.[143]

Primary Task Performance. The primary task performance measure assesses the subject's performance on standard work tasks (e.g., cases seen, knots tied, etc.) as they are made progressively more difficult by increasing the number of tasks, task density, or task complexity. At first, the subject is able to keep up with the increasing task load, but at some point, the workload exceeds the ability to manage it, and performance on the standard tasks decreases.

Secondary Task Probing. Secondary task probing tests the subject with a minimally intrusive secondary task that is added to the primary work tasks. The secondary task is a simple one for which performance can be objectively measured. Reaction time, finger tapping, mental arithmetic and a vibrotactile device have for example been used for this technique as a secondary task. The anesthesia professional is instructed that the primary tasks of patient care take absolute precedence over the secondary task. Therefore, assuming that the secondary task requires some of the same mental resources as the primary task, the performance of the anesthesiologist on the secondary task is an indirect reflection of the spare capacity available to deal with it: the greater the spare capacity, the lower the primary workload. Depending on the secondary task response channels (manual, voice, gesture, multiple ways) there can exist channel interference. Controversy exists about whether these probes measure "vigilance" or "workload," although the same techniques probably measure both aspects of performance. When probes occur infrequently, are subtle, have multiple response channels, and are performed with a low level of existing workload, they are more likely to measure vigilance; when they are frequent, readily detectable, require a manual response, and are performed during a high-workload period, they probably are more indicative of spare capacity and workload.

Subjective Measures. In subjective measures, individuals are asked, most commonly in retrospect but sometimes in real time, how much load they were or are under during actual work situations. A common and validated form to assess subjective workload is the NASA TLX form.[140] Subjective measures usually complement objective measurements of external observations, since an anesthesia professional may subjectively underestimate the workload in settings in which objective measurements demonstrate a marked reduction in spare capacity.

Physiologic Measures. The final set of techniques for assessing workload consists of physiologic measures. Visual or auditory evoked potentials have been used successfully to assess mental workload, but this technique can be used only in a static laboratory environment. Heart rate (especially certain aspects of heart rate variability) and blood pressure are other physiologic measures that have been used, but there are challenges in reliable interpretation.

ASSESSING THE PERFORMANCE OF ANESTHESIA PROFESSIONALS

Over the years several study designs investigating manual (i.e., technical aspects of a procedure), cognitive (i.e., dynamic decision making, situation awareness, vigilance) and behavioral/nontechnical (i.e., communication, teamwork, leadership) tasks were used to assess the performance of anesthesiologists. In this section, studies with special focus on anesthesia professional's performance about action density, work experience, teaching/delegation/supervision activity, and critical incidents/emergency treatment are presented. Most of the studies were performed in a simulated medical environment.

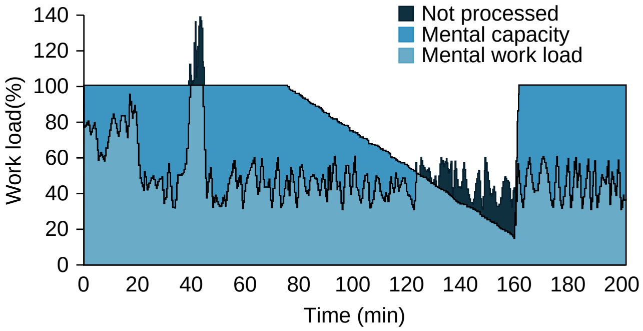

Fig. 6.2 Illustration of how mental workload for the individual and the team may vary during anesthesia. Time is shown on the x-axis. Total workload is shown on the y-axis. During the first 20 minutes of anesthesia induction the workload is high, but does not exceed mental capacity. Then, during the first minutes of maintenance the workload drops. At 35 minutes a crisis leads to a sudden increase in workload, which exceeds mental capacity. As shown, during this time certain information is not processed. Such a sudden overload is a typical feature of critical incidents, known in aviation as "maxing out." Thereafter, the workload of the maintenance phase drops again. But at the same time, after around 80 minutes in the case, the anesthesia professional becomes progressively more tired, resulting in less mental capacity available. So between 120 and 160 minutes workload again exceeds mental capacity and information is not processed. Finally, the anesthesiologist is roused after 160 minutes and workload again lies within capacity until the end of the case. (Figure based on the publication of Byrne A. Measurement of mental workload in clinical medicine: a review study. *Anesth Pain Med.* 2011;1(2):90–94.)

Because much of the more recent literature recapitulates findings of the pioneering studies, in this chapter those initial studies are used but the reader also is referred to newer, selected studies, without providing an exhaustive list.[6-8,68,73,74,76,144-149] The latest, large-scale study concerning the performance of anesthesiologists was published by Weinger and co-workers in 2017, examining the performance of board-certified anesthesiologists during four emergency cases.[75] The study is also presented in detail below.

A broader view on general human performance aspects related to anesthesia can be found in the next sections on "human performance, human factors and nontechnical skills" and "system thinking."

Performance as a function of task density

It is generally accepted that there are limits on human ability to process information, and that information overload can lead to poor performance.[150] For example, many people will have experienced the difficulties of simultaneously trying to drive, navigate, read road signs, and listen to passengers. However, the work domain of anesthesia oftentimes seems to require exactly this kind of task density (Fig. 6.2). An interdisciplinary research group performed several task analysis studies, which allowed the analysis of multiple parallel and overlapping actions (action/task density).[89] Figs. 6.3 and 6.4 show examples of observations of 24 real OR studies. The observation data contain many short-term fluctuations *(dots)*; the moving average of action density of the previous 5 minutes was charted as well *(line)*. Fig. 6.3 shows a complete anesthesia procedure with increases in action density during induction and emergence from anesthesia. Fig. 6.4 shows two final phases of cardiac cases

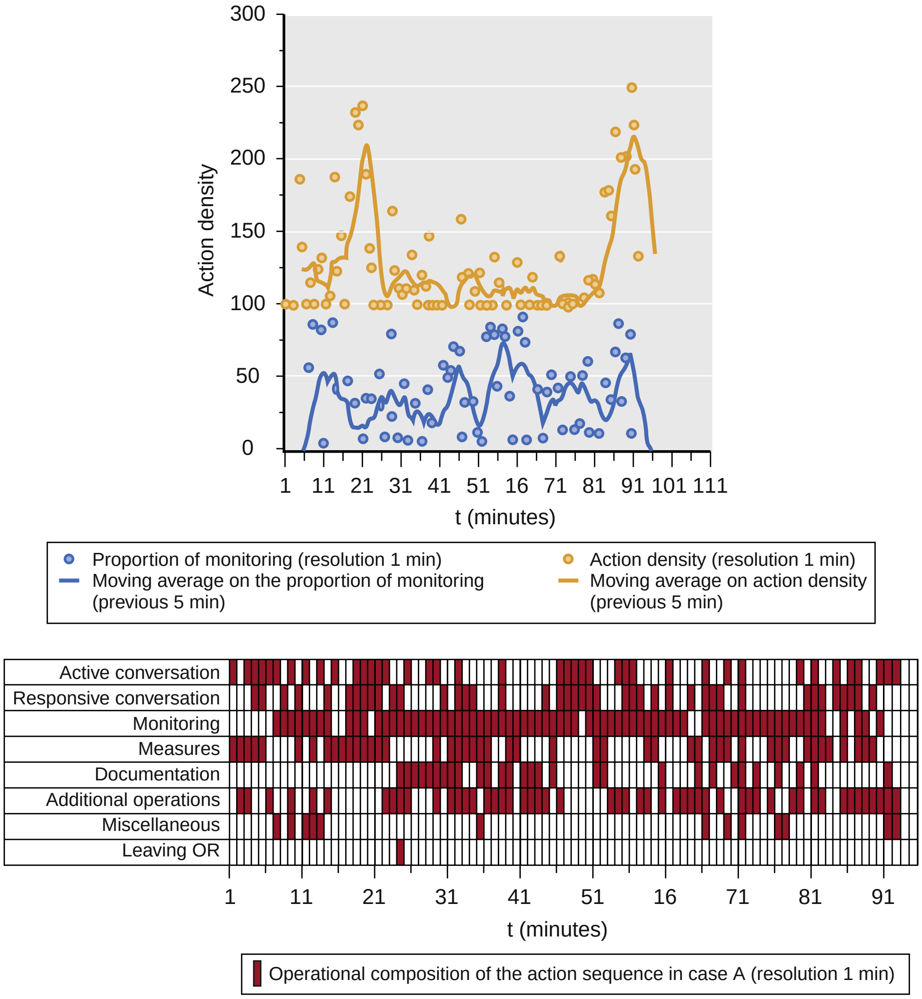

Fig. 6.3 Action density diagram illustrating the derived parameter "action density" from induction of anesthesia to emergence in a real anesthetic case. The *yellow line* in the graph shows the overall action density and the *dots* show the moving average of the density. The *blue line* shows the contribution of one task group, "monitoring," as an example. The table in the lower graph shows the composition of the data for all eight task groups from the same case. *OR,* Operating room.

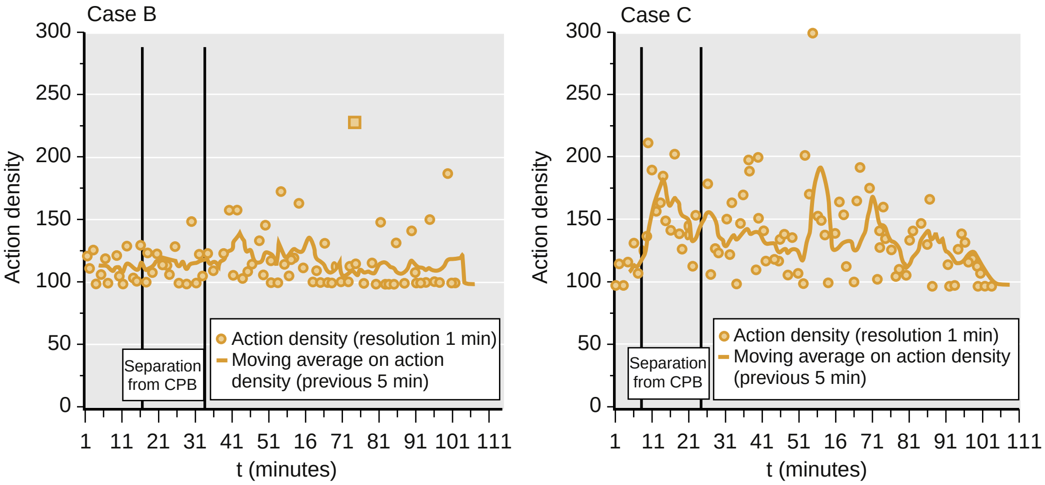

Fig. 6.4 Action density during separation from cardiopulmonary bypass without and with complications. The graph on the *left* is the density diagram of an uncomplicated case (case B) with a "flat" action density diagram during (between the two *vertical lines)* and after separation from cardiopulmonary bypass (CPB). In contrast, case C, shown in the graph on the *right,* had a complicated weaning from CPB; a very high action density is followed by an elevated density with further peaks after separation.

involving cardiopulmonary bypass. The described task analysis technique was also used to study action sequences in simulated cases and compare them with findings in the real OR to demonstrate and evaluate the ecologic validity of simulators (see Chapter 7).[64,89] Findings indicated that as the density of tasks per unit time increased, the dwell time on each task decreased, and vice versa. This finding has important implications for how anesthesia professionals allocate their attention.

Another interesting aspect in this respect is the hypothesis that the mental workload of novices may be lower than that of more experienced staff because they have yet to appreciate the difficulties facing them; this is termed unconscious incompetence.[151]

Xiao and colleagues[70] used simulations to investigate the dimensions of task complexity and their impact on crisis activities and team processes in the trauma room. They identified four components of complexity that affected team coordination in different ways. Multiple concurrent tasks led to goal conflict, task interference, and competition for access to the patient. Uncertainty regarding the case led to differences in opinion when interpreting information and difficulties when trying to anticipate the actions of other team members. The use of contingency plans caused difficulty in knowing when to switch tasks and how then to reallocate activities. Finally, a high workload caused procedures to be compressed and this deviation from normal work further increased the complexity of the situation. They suggested training in explicit communication to meet the challenges of task complexity.

Performance as a Function of Teaching, Delegation, and Supervision

Teaching. Close interaction of experienced anesthesia professionals with inexperienced clinical trainees during actual surgical procedures is a standard approach to training. It can be hypothesized that teaching adds to the workload of the more experienced care provider who is simultaneously responsible for safe and efficient anesthesia care during the procedure. Weinger and co-workers[92] found that teaching teams, involving one-to-one supervision of fourth-year medical students or first-month anesthesia residents by an attending anesthesiologist, had significantly slower response times to a warning light than non-teaching teams of attending(s) of similar experience. Response latency was highest during induction and emergence. This vigilance test was also a procedural (performance) workload assessment measure indicating increased workload and reduced spare capacity. They also found that workload density was significantly increased for teaching as opposed to non-teaching teams. In sum, intraoperative teaching increased workload and decreased vigilance, suggesting the need for caution when educating during patient care.

Delegation and Supervision. Experience suggests that the effect of delegation on workload varies depending on the nature of the task and how confident the delegating anesthesia professional feels about the capability of the person to whom the task is assigned. Delegation must be guided by the supervisor's situation awareness and overall ability to process information on the patients' condition. Several further aspects are presented in the work of Leedal and Smith.[142]

Performance as a Function of Experience

Routine Events. Novice trainee anesthesia professionals were found to perform many of the same tasks as do more experienced personnel at specific phases of an anesthetic regimen, but take longer over tasks, show longer latency of response, and greater task workload than third-year trainees and experienced nurse anesthetists.[90] While task density was generally highest for both subject groups in the period up to, during, and immediately after intubation, the more experienced trainees had higher task densities than the novices, suggesting greater competence among the former in carrying out multiple tasks in a short period of time. Those findings are in line with other studies, including the study of Weinger and associates[67] that evaluated the mean response time of pressing a buzzer at the flashing of a red light (secondary task). The response time was markedly less than 60 seconds for experienced subjects in both the induction and post induction (maintenance) phases, but it was much higher for novice residents during the induction phase. One explanation for those findings may be that the reduction of workload depends partly on the degree to which tasks can become routine, thus freeing mental resources for other tasks. Leedal and Smith conclude concerning this matter in their review: *"Experienced staff appear to show 'spare capacity' in performance during routine cases, which we suggest allows them an attentional 'safety margin' should adverse events occur"* (p. 708) [142]

In contrast, a more recent study presented by Byrne and co-workers found there was limited evidence of a relationship between workload and experience.[152]

Another recent finding indicates that more experienced anesthesia teams may be more likely to attempt to coordinate implicitly, without much overt communication, which makes them more reliant on accurate and shared understandings of the task and their teamwork.[153]

Novice residents also spent more time speaking to their attending staff (11% of preintubation time) than did experienced residents or CRNAs.[90] Experienced personnel observed the surgical field more than did the novices. Novices did take longer to complete patient preparation and induction of anesthesia, but it appeared that some of the extra time taken by novices working under supervision was offset by the efficiency of offloading other concurrent tasks to the attending anesthesiologist such that preintubation time was increased by only 6 minutes for novices.

Critical Events/Emergencies. Schulz and colleagues[97] presented data where more experienced anesthetists (>2 years work experience) increased the amount of time dedicated to manual tasks from 21% to 25% during critical incidents, whereas the less experienced decreased from 20% to 14%. The less experienced anesthesia providers spend more time on monitoring tasks.

A study by Byrne and Jones [76] looked at differences in the performance of experienced and less experienced anesthesia professionals during 180 simulated anesthesia emergency scenarios. The results showed significant differences only between the first and second year. As seen in other studies, significant errors occurred at all levels of experience,[75,76,125,126] and most of the anesthesia professionals deviated from established guidelines.[75,76,154]

A classic simulation study by DeAnda and Gaba investigated the response of anesthesia trainees and experienced anesthesia faculty and private practitioners to six preplanned critical incidents of differing type and severity.[126,155] The incidents included (1) endobronchial intubation (EI) resulting from surgical manipulation of the tube; (2) occlusion of intravenous (IV) tubing; (3) atrial fibrillation (AF) with a rapid ventricular response and hypotension; (4) airway disconnection between the endotracheal tube and the breathing circuit; (5) breathing hoses too short to turn the table 180 degrees, as requested by the surgeon; and (6) ventricular tachycardia or fibrillation. For each incident, considerable interindividual variability was found in detection and correction times, in information sources used, and in actions taken. The average performance of the anesthesia professionals tended to improve with experience, although this varied by incident. The performance of the experienced groups was not better than that of the second-year residents (who were in their final year of training at that time). Many (but not all) novice residents performed indistinguishably from more experienced subjects. Each experience group contained some who required excessive time to solve the problem or who never solved it. In each experience group at least one individual made major errors that could have had a substantial negative impact on a patient's clinical outcome. For example, one faculty member never used electrical countershock to treat ventricular fibrillation. One private practitioner treated the EI as though it were "bronchospasm" and never assessed the symmetry of ventilation. One resident never found the airway disconnection. The elements of suboptimal performance were both technical and cognitive. Technical problems included choosing defibrillation energies appropriate for internal paddles when using external paddles, ampule swap, and failure to inflate the endotracheal tube cuff that resulted in a leak. Cognitive problems included failure to allocate attention to the most critical problems and fixation errors.

Schwid and O'Donnell[125] performed an experiment similar to those of DeAnda and Gaba and received similar results. After working on several practice cases without critical incidents, each subject was asked to manage 3 or 4 cases involving a total of 4 serious critical events (esophageal intubation, myocardial ischemia, anaphylaxis, and cardiac arrest). The anesthesiologists studied had varying experience levels. Significant errors in diagnosis or treatment were made in every experience group. The errors occurred in both diagnosis of problems and in deciding on and implementing appropriate treatment. For example, 60% of subjects did not make the diagnosis of anaphylaxis despite available information on heart rate, blood pressure, wheezing, increased peak inspiratory pressure, and the presence of a rash. In managing myocardial ischemia, multiple failures occurred. 30% of subjects did not compensate for severe abnormalities while considering diagnostic maneuvers. Fixation errors in which initial diagnoses and plans were never revised were frequent, even when they were clearly wrong.

Independent from professionals' experience, Howard and colleagues[127] found a substantial incidence of difficulties during simulated emergencies: managing multiple problems simultaneously, applying attention to the most critical needs, acting as team leader, communicating with personnel, and using all available OR resources to best advantage. Analysis of videotaped trauma and resuscitation cases has revealed inadequacies in the availability and arrangement of monitoring equipment, as well as nonexistent or ambiguous communication.[69] Byrne and Jones [76] evaluated the performance of anesthetists during nine emergency cases, showing that serious errors in both diagnosis and treatment were made and accepted treatment guidelines were not followed. Diagnosis of several common critical incidents, for example, anaphylaxis, was hard to name.[74,125] As described earlier, once diagnosed, no structured plans or algorithms were used.[73,74]

These classic studies date back 25 years or more, yet the most recent studies [75,156] remain completely consistent with older studies. In the 2017 Weinger and colleagues publication, a total of 263 consenting U.S. board-certified anesthesiologists (BCAs—i.e., physicians) participated in two, 20-minute, standardized, high-fidelity simulation scenarios of unanticipated acute events during existing Maintenance of Certification in Anesthesiology simulation courses. The scenarios were from among the following: (1) local anesthetic systemic toxicity with hemodynamic collapse; (2) hemorrhagic shock due to hidden retroperitoneal bleeding during laparoscopy; (3) malignant hyperthermia presenting in the postanesthesia care unit; and (4) acute onset of AF with hemodynamic instability during laparotomy followed by ST elevation myocardial infarction. Performance measurement rubrics were established in advance: a scoresheet of critical clinical performance elements, behavioral anchored ordinal scales of four nontechnical skills, ordinal scales for overall individual and team technical performance and nontechnical performance, and a binary rating as to whether performance met or exceeded that expected of a BCA. The results showed that critical clinical performance elements were commonly omitted, roughly in four broad areas of crisis management, failures to: (1) escalate therapy where first-line options did not work (e.g., using epinephrine or vasopressin when phenylephrine, ephedrine, or fluids did not sufficiently correct hypotension); (2) use available resources (e.g., calling for help when conditions have deteriorated appreciably); (3) speak up and engage other team members, especially when action by them was required (e.g., asking the surgeon to change the surgical approach when it is essential to effective treatment); and (4) follow evidence-based guidelines (e.g., giving dantrolene to a patient with obvious MH). The performance of approximately 25% of subjects was rated in the low portion of the various technical and nontechnical 9-point ordinal scales. In about 30% of encounters, performance was rated as "below the level expected of a BCA."

PATIENT SAFETY ACTION BOX

Experienced anesthetists are not immune to error. Studies show that significant errors can occur at all levels of experience. *Experience is not a substitute for excellence or expertise*, making recurrent training and continuous awareness of possible safety pitfalls important, independent of the experience level.

PATIENT SAFETY ACTION BOX

Do not think this cannot happen to you… In her paper, "Lake Wobegon for anesthesia...where everyone is above average except those who aren't: variability in the management of simulated intraoperative critical incidents," McIntosh[157] discusses the applicability to anesthesiology of the pervasive human tendency to overestimate one's achievements and capabilities in relation to others. Such effects have been documented for drivers, CEOs, stock market analysts, college students, parents, and state education officials, among others.[158] Indeed we may all be living in Lake Wobegon in terms of evaluating our own abilities to manage critical events.

What are the practical implications of performance assessment in Anesthesia?

In summary, simulation studies on performance all showed appreciable performance gaps of anesthesia professionals managing critical incidents and emergencies. The results expand on the few comparable data on real cases.[159-163] Overall, the surprisingly high frequency of mediocre performance represents a patient safety concern for the field of anesthesiology, emphasizing the need for anesthesia professionals and their organizations to:

- be aware of performance shortcomings and pitfalls in everyday work
- regard the knowledge and training of performance-enhancing strategies as one of the core competencies
- focus on the application of and adherence to evidence-based practice guidelines
- focus on the efficient management of the environment (team, resources, equipment, etc.)
- implement case management skills in the education, training, and re-certification, that go beyond only medical/technical knowledge and skill

BENEFITS AND CHALLENGES OF ASSESSING PERFORMANCE

Benefits of the Scientific Study of Tasks and Performance in Anesthesia

The generation of an improved understanding of the human performance of anesthesia professionals can help them to provide patient care more safely, in a wider variety of clinical situations, with greater efficiency, and with increased satisfaction to both patients and practitioners. The possible benefits of studying human performance include, but are not limited to, the following:

1. Improved clinical performance: Behavior observation helps to identify which processes and behaviors are associated with effective and safe performance.[63,83,164] Thus, it provides us with new knowledge on what effective teams do differently compared with ineffective teams and how they do it.[165] Compared with self-reports, behavior observation allows for measuring actual team-level phenomena and dynamics that teams may not even be aware of and that may unfold over time.[166]
2. Improved operational protocols: The way in which individuals conduct anesthesia is based, in part, on knowing the limits of their performance envelope. Anesthetic techniques and OR practices should draw on anesthesia professionals' abilities and should mitigate their weaknesses.
3. Enhanced clinical education and training of anesthesia professionals: Understanding the required performance characteristics and inherent human limitations will lead to improved training, which will most fully develop the strengths and counter the existing vulnerabilities of the anesthesia professional. Identification of performance gaps informs opportunities for improvement.[75] Identification of expert knowledge through elicitation of unaware expertise behavior creates educational gain.[167] Taking this knowledge into action should make patient care safer, less stressful, and more efficient.
4. A more effective work environment: Anesthesia professionals now perform their tasks by using an array of technologies, many of which have not been designed to support the anesthesia professional's work optimally. By understanding the relevant tasks and performance requirements, the workspace and tools could be improved for better support of the most difficult tasks. This, too, can lead to greater safety and to greater efficiency and work satisfaction.
5. A more efficient organizational system: Anesthesiology is embedded within a larger system of organized medical care that involves interactions among numerous people, institutions, organizations, and professional domains. Understanding how the anesthesia professional's work relates to the larger system may enable the development of more rational and efficient flow of information and organizational control.
6. A more rational view of professional work and legal responsibility: Modern health care, especially in the United States, is strongly influenced by medicolegal concerns. The litigation system has a major selection bias in that every case that comes before it involves an adverse outcome for a patient. The duty of the practitioner is to render care as a reasonable and prudent specialist in the area of anesthesia. What is reasonable and prudent? What type of performance is to be expected from appropriately trained human beings in a complex and dynamic environment? By understanding human performance, it may be possible to generate a more rational view of what is and is not within the standard of care.

Challenges of the Scientific Study of Tasks and Performance in Anesthesia

Study of human performance involves research paradigms different from those typically used in the science of anesthesia. Many obstacles exist to obtaining valid data on human performance. There are no animal models for expert human performance and no Sprague-Dawley anesthesia professionals to be studied in detail. Recruiting experienced personnel to be the subjects of study is difficult and raises issues of selection bias concerning those who do volunteer. Especially if conducted during actual patient care, investigations of human performance are strongly influenced by concerns about litigation, credentialing, and confidentiality, thus making it difficult to execute optimal studies. Furthermore, variability among individual anesthesia professionals is quite striking because different anesthesia professionals respond to the same situation in different ways, and each individual may act differently on different days or at different times of the same day. The magnitude of this intraindividual variability is often nearly the same as the interindividual variability. Another challenge is that the performance measures may not be sensitive to an increase or decrease in workload if the subject compensates through increased, or reduced, effort respectively.

Performance itself is an intuitively meaningful concept that is difficult to define precisely. No universal standards are available for the clinical decisions and actions of anesthesia professionals. They depend heavily on the context of specific situations. In addition, determining how anesthesia professionals perform their jobs, whether successfully or unsuccessfully, means delving into their mental processes. This cannot be measured easily. Experimental designs can involve artificial laboratory tasks for which performance can be objectively measured, but these tasks will then be far removed from the real world of administering anesthesia. Conversely, investigating the actual performance of trained practitioners in the real world yields primarily subjective and indirect data. Understanding the anesthesia professional's performance must be seen as analogous to solving a jigsaw puzzle, an analogy introduced by Gaba[128] and extended by McIntosh.[157] Pieces of the puzzle probably come from a variety of sources, none of which by itself captures the entire picture.

Problems faced by all investigators are the lack of an accepted standard for objective or subjective evaluation of anesthesia professional performance and the absence of an agreed-on methodology for analyzing and describing anesthesia professional performance. As one result of the divergent research landscape in human performance, the number, scope, and variety of applied behavior observation taxonomies are growing, making comparison and convergent integration of research findings difficult. Several groups were working on methodologies for evaluating technical and behavioral aspects of performance.[75,89,166,168-170]

Kolbe and colleagues[166] pointed out four methodological challenges when rating behavior. First is identifying the optimal balance between specificity versus generalizability. Researchers must decide whether to investigate processes from a general perspective using methods that capture all teamwork behaviors simultaneously or whether to focus on one single process (e.g., closed-loop communication) to explore it in detail. Second is deciding whether to rate the quality or describe the occurrence of teamwork behavior. Quality of behavior can be measured with an anchored ordinal rating scale (e.g., from excellent to poor). Or alternatively, the occurrences of particular behaviors can be measured such as when?—by whom?—to whom?, etc., delivering different results. Third is linking research findings with team training content, when no common language and no common behavioral codes, respectively, are used in research. Fourth is applying different rating systems (in different studies) without respect to the usability and the different requirements for research, training, and examination purposes.

Patient Safety on the Individual and Team Level

In earlier sections the characteristics of the complex and dynamic working environment in anesthesia were described in detail, as well as the multiple manual, behavioral, and cognitive tasks and related performance assessment studies of the anesthesia professional. Both sections illustrated several human performance and patient safety challenges that personnel face regularly. The knowledge and management of the complex work environment and the various tasks, workload, and performance pitfalls can determine the ultimate success of professionals' intervention. These human factors comprise issues related to perception, memory, problem solving, physiological rhythm, and more. This section focusses on the so-called nontechnical skills and performance-shaping factors [37,38,136,171-174] as they have the most direct practical impact for the work of anesthesia professionals.

The importance of nontechnical skills and performance-shaping factors is also in line with the performance studies of anesthesiologists mentioned earlier in this chapter.[69,70,73-76,125,127] They revealed room for improvement at any level of experience, especially in non-routine and emergency situations. Recent views on nontechnical skills emphasize their relevance also in routine situations to prevent those from becoming critical.[175] Nontechnical skills explain difficulties in applying knowledge and skills that team members possess in stressful moments in a dynamic, complex, and high-workload environment. They are related to challenges in managing and coordinating oneself (e.g., remembering to do tasks, monitoring one's own actions, acting as a team leader), the team (e.g., distributing tasks, managing conflict, sharing mental models), and the equipment (e.g., knowing the application of the equipment, understanding different use modes, troubleshooting).

Therefore, in the upcoming sections the following topics are addressed: (1) General concepts of human factors (HF) and nontechnical skills (NTS) are introduced and discussed in the larger context of human performance. Subsequently, several examples of the impact of HF/NTS are given, indicating that from a safety point of view, HFs and NTS deserve as much attention as medical knowledge [patho-] physiology, diagnosis, treatment) and practical skills, which by tradition have dominated training programs for anesthesia professionals. (2) Two sets of key elements of patient safety: first relating to individual performance (situation awareness and decision making), and second relating to team performance (communication, teamwork, and task management). (3) Additionally, individual performance-shaping factors are discussed, in particular fatigue, interruptions, distractions, and ambient noise.

HUMAN PERFORMANCE, HUMAN FACTORS, AND NONTECHNICAL SKILLS

In the literature, the interrelated terms human performance, human factors, and nontechnical skills are used in a variety of ways and sometimes even synonymously, making it difficult to classify them. They are interconnected and while several models and taxonomies exist there is not always a clear distinction between these terms and concepts. In the upcoming section the authors explain the general underlying principles and give a simplified overview of their interrelationships in order to generate a more systematic understanding of key concepts. The term human error, also used in this context occasionally, is itself a different term, almost the flipside of human factors. One might say that challenges in human factors (and other aspects) can result in human error. For the definition and classification of human error see later section on "System Thinking."

HUMAN PERFORMANCE AND HUMAN FACTORS

What are Human Factors? Human performance is shaped, positively or negatively, by different levels of so-called human factors (HF). Good HF increases and poor HF decreases human performance. The term ergonomics is also used in some contexts. A broad variety of disciplines are involved and many different topics are embraced by both terms; hence, several definitions exist. The Human Factors and Ergonomics Society defines HF as follows: *"Human factors is concerned with the application of what we know about people, their abilities, characteristics, and limitations to the design of equipment they use, environments in which they function, and jobs they perform."*[176] Catchpole and McCulloch define human factors in the medical context as: *"Enhancing clinical performance through an understanding of the effects of teamwork, tasks, equipment, workspace, culture, and organization on human behavior and abilities and application of that knowledge in clinical settings."*[177]

Different Components of Human Factors. Derived from the SEIPS model[178,179] and adapted by the authors, different components of HF are:

- the behavior of individuals and their behavior/knowledge in regard to tasks (individual level)
- the interactions with each other (team level)
- the interactions of professionals with the organizational/sociocultural conditions (organizational level)
- the interactions of professionals with the environment/workspace (environmental level) and
- the interactions of professionals with technology/equipment (technology/engineering/design level)

Those five human factor components are necessary and sufficient to describe and understand the anesthesia professional's entire work system from a HF perspective. The components interact with and influence each other, resulting in a large number of relationships between different levels. At times the components compensate each other (e.g., when professionals work faster to compensate for time pressure or when people collaborate to solve problems that are beyond an individual's abilities). Other times the components resonate with each other and amplify their effects—for the good (e.g., having the right equipment for the task at hand) or the bad (e.g., lacking resources to solve a problem). Given that this chapter cannot deal with human factors in a comprehensive way, many topics can be touched on only briefly. Although the environmental and technology levels can be important—cognition is challenged when there is a power failure or a breakdown of key clinical equipment—in this chapter the focus lies on the most important aspects of human factors directly relevant to anesthesia professionals: the individual level, team level, and organizational level.

HUMAN FACTORS AND NONTECHNICAL SKILLS

What are NonTechnical skills in comparison to Human Factors? When talking specifically about HF that are directly related to actions of a single individual and/or of a team, often this is referred to as the concept of nontechnical skills (NTS). NTS are defined as *"the cognitive, social, and personal resource skills that complement technical skills (which encompass the technical knowledge of health care and its various procedures), and contribute to safe and efficient task performance"*[11] or alternatively as *"attitudes and behaviors not directly related to the use of medical expertise, drugs, or equipment."*[171]

While some authors object to the term nontechnical skills—using a negative to describe something—others have pointed out that not only is this term in wide use already, but that actually a variety of terms involving negation are in common use in science, mathematics, and medicine. One main paper and an editorial discuss this issue.[180,181] For health care, instead of nontechnical skills, the term could also be non-medical skills. However, because of the extensive use of nontechnical skills in the literature of other industries and in health care, this chapter uses that terminology.

Different Ways to Categorize NonTechnical Skills. In general, NTS can be categorized into two broad areas: (1) *cognitive and mental skills* on the individual level, including decision making and situation awareness; and (2) *social and interpersonal skills* on the team level, including teamwork, communication, and leadership. Commercial aviation incorporated such nontechnical skills in the cockpit (later crew) resource management paradigm (CRM, 1980s and continuous later evolution) and the "NOTECHS" paradigm in the late 1990s. In anesthesiology, the anesthesia crisis resource management (ACRM) framework was introduced by Howard and co-workers in 1990[127] as an adaptation of aviation's CRM. The ACRM approach categorizes NTS based on the five key elements of communication, situation awareness, decision making, teamwork (implicitly including leadership), and task management (Fig. 6.5). The anesthesia nontechnical skills (ANTS) framework by Fletcher and colleagues was introduced in 2003; Flin and colleagues give an overview of its history, development, application, use, and emerging is issues.[182, 183] The ANTS approach typically includes the four categories of situation awareness, decision making, teamwork (explicitly including leadership), and task management. Neither of these frameworks, and indeed no usable paradigm, can capture explicitly every important aspect of HF applied to anesthesiology. For example the management of the performance-shaping factors stress and fatigue are also part of the ANTS framework, but are implicit in ACRM. Communication itself is not an explicit skill element of the ANTS framework (which assumes that communication pervades each element), whereas in ACRM it is a specific skill that needs explicit mention and training.[184] Of note, from their start in anesthesiology, nontechnical skills frameworks have been further adapted to several other medical fields, such as for surgeons and intensive care specialists.[8,11,168,169,185-188]

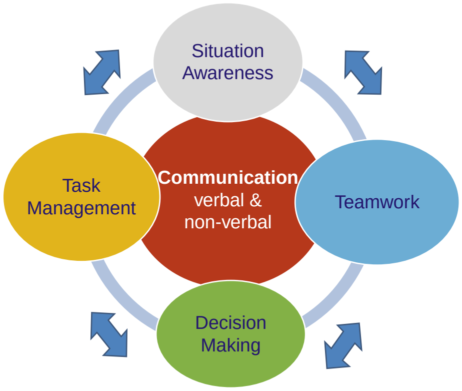

Fig. 6.5 The five main elements of Crisis Resource Management (CRM). The main elements include: Communication, situation awareness, decision making, task management, and teamwork. In this approach, effective communication is like the glue that holds all the other components together. Besides, all the components are intertwined with and related to each other, indicated by the arrows between the elements.

Assessment of NonTechnical Skills. In response to the growing acceptance of human factors and nontechnical skills influencing medical performance, several rubrics to measure NTS have been developed. Gaba and colleagues in 1998 described the direct adaptation for assessment of NTS of a set of CRM-anchored ordinal scale markers from Helmreich et al. concerning aviation.[169,189] In 2004 the ANTS framework was complemented by a behaviorally anchored rating scale in 2004.[182,183] A new set of assessment scales for four markers of NTS was introduced by Weinger and colleagues [75] in 2017 based on the fusion of aspects of a number of prior approaches.

A further, rather new approach for the assessment of nontechnical skills is the Co-ACT framework described by Kolbe and co-workers.[166] The framework serves observing coordination behavior, especially in acute care teams like anesthesia, and consists of four categories, each category obtaining three further subelements that more specifically describe the NTS: (1) *explicit action coordination* with the elements *instruction, speaking up*, and *planning*; (2) *implicit action coordination* with the elements *monitoring, talking to the room* (action-related), and *providing assistance*; (3) *explicit information coordination* with the elements *information request, information evaluation*, and *information upon request*; and (4) *implicit information coordination* with the elements *gathering information, talking to the room (information-related)*, and *information without request*.

Challenges of the Assessment of NonTechnical Skills. The psychometric qualities of measuring NTS have been assessed by the developers of the ANTS system and were considered to be of acceptable level,[182] whereas another study[190] assessed the reliability after a 1-day training for raters and concluded that reliability was poor. A study from Denmark showed good psychometric qualities.[185] Originally developed for educational purposes and used to discuss the NTS of anesthesiologists after training sessions in order to improve in NTS, Zwaan and colleagues assessed the usability and reliability for ANTS in research, finding that the ANTS system was reliable for the total score and usable to measure physicians' NTS in a research setting.[191] However, the investigators found a variation between the reliability of the different elements and recommend excluding elements in advance that are not applicable or observable in the situation of interest. It might not always be easy, however, to identify those elements that should be excluded. On the whole, the ANTS system appears to be a useful tool to enhance assessment of nontechnical skills in anesthesia and other medical fields further, and its careful derivation from an established system of nontechnical assessment in aviation (NOTECHS) may even allow some interdomain comparisons. However, more recently Watkins and colleagues directly compared ANTS with the system used in the Weinger and colleagues 2017 paper [75] and showed that ANTS was more difficult to use but that the two systems otherwise achieved equivalent assessment results.[192]

NonTechnical Skills: The Bad - The Good - The Variable. Good nontechnical skills (i.e., vigilance, efficient communication, team coordination, etc.) reduce the likelihood of active and passive errors and adverse events, and also increase human performance, whereas suboptimal NTS are expected to do the reverse. These effects are variable; for example, a person may communicate very effectively in one instance and fail to do so in the next challenging communication role.

A study from Denmark investigated the relationship between technical and nontechnical skills.[193] Twenty-five video recordings of second-year anesthesiologists managing a simulated difficult airway management scenario were rated with the ANTS instrument[185] and a score for the technical aspect for the procedure. In addition, written descriptions of the NTS performance were collected and content analyzed. The correlation between the two scores was not significant, but the content analysis comparing the NTS description in the best and poorest three scenarios identified what contributed most to good NTS. These were systematically collecting information, thinking ahead, communicating and justifying of decisions, delegating tasks, and vigilantly responding to the evolving situation. Poor NTS were related to: lack of structured approach, lack of articulating plans and decisions, poor resource and task management, lack of considering consequences of treatment, poor response to the evolving situation, and lack of leadership.

What is the Impact of Non-Technical Skills and Human Factors on Poor Performance in Medicine? The impact of poor NTS on poor human performance in the medical field cannot be overestimated. Depending on the literature, it is estimated that up to 80% of all errors in medicine can be attributed to problems with NTS and human factors.[37,38,171-174]

Even though one can argue on the one hand that due to progress in technology the findings and estimates of the pioneer study of Cooper and colleagues[37] performed in 1978 (results relating up to 80% of incidents to human factors) have been outdated for a long time, on the other hand those figures are (1) comparable to findings in other dynamic and complex work environments[171] and (2) newer studies as recent as 2015 still reconfirm those findings (references see below). In the following some illustrative studies are mentioned that link HF and safety challenges.

In 1993 an analysis of 2000 incident reports from the Australian Incident Reporting Study took place, investigating the incidents for relations to human factors and NTS.[38] In 83% of incidents, human factor elements were scored by the reporters. Even though scoring by the incident reporters might not produce results as accurate as those of a systematic scoring by human factor experts and such text descriptions are of limited value for this type of data collection, it still shows the scope of the problem—having also in mind that voluntarily reported incidents only represent the peak of an iceberg, with many incidents not reported at all.

Fletcher and colleagues published a review of studies describing the influence of nontechnical skills in anesthesia in 2002, summarizing that it is clear "*that nontechnical skills play a central role in good anesthesia practice and that a wide range of behaviors are important […] [including] monitoring, allocation of attention, planning and preparation, situation awareness, prioritization, applying predefined strategies/protocols, flexibility in decision-making, communication, and teamworking*" [p.426].[171]

As increasing evidence suggested that human factors like communication, leadership, and team interaction influence the performance of cardiopulmonary resuscitation (CPR), Hunziker and colleagues[6] presented a study in 2010 reviewing the impact of human factors during simulation-based resuscitation scenarios. Similar to studies in real patients, simulated cardiac arrest scenarios revealed many unnecessary interruptions of CPR as well as significant delays in defibrillation—two outcome-relevant parameters. The studies showed that human factors played a major role in these shortcomings and that medical performance, at least in non-routine situations, depends among others on the quality of leadership and team-structuring.

Jones and co-workers[194] only recently systematically reviewed the literature on the impact of HFs in preventing complications in anesthesia due to poor airway management and highlighted recent national reports and guidelines, including the 4th National Audit Project (NAP4). NAP4 (2011) was the first prospective study of all major airway events occurring throughout the UK, reviewing any complications resulting from airway management that led to either death, brain damage, the need for an emergency surgical airway, unanticipated ICU admission, or prolongation of ICU stay.[173] 184 reports were reviewed. Subsequent in-depth analysis identified HFs as having been a relevant influence in every case, with a median range of 4.5 contributing HFs per case.[195] HFs in the report included for example[173]: casual attitude toward risk/overconfidence, peer tolerance of poor standards, lack of clarity in team structures, poor or dysfunctional communication including incomplete or inadequate handovers, inadequate checking procedures, failure to formulate back-up plans and discuss them with team members, failure to use available equipment, attempts to use unknown equipment in an emergency situation, heavy personal workload, lack of time to undertake thorough assessment, equipment shortage, inexperienced personnel working unsupervised, organizational cultures which induce or tolerate unsafe practices, no formalized requirement to undertake checking procedures, incompatible goals, and reluctance to analyze adverse events and learn from errors.

The Sentinel Event Report of the Joint Commission analyzed the root causes of 764 sentinel events (patient's death, loss in function, unexpected additional care and/or psychological impact) reported voluntarily in 2014.[172] Human-factor-related root causes, including among others communication and leadership, were the leading root causes of sentinel events and made up 65% of root causes. Even though the data are not specifically linked to anesthesia practice, it is very likely that there exist strong parallels.

One of the latest simulation-based studies, performed by Weinger and colleagues [75] in 2017 and explained in detail earlier (section on assessing performance, "Performance as a Function of Experience"), also shows a broad variety of human-factor-related hurdles for anesthesiologists when handling emergencies.

What are the implications of the Impact of Humand Factors and NonTechnical Skills on Human Performance?

- Balancing the importance of technical and non *technical skills during medical education and training.* While technical skills and medical knowledge have always been at the core of medical education and training, the importance of NTS has—despite long growing evidence—only recently been recognized.
- *Acknowledgement of the importance of human factors as individual and team.* One of the first steps for individuals and teams in minimizing and mitigating human frailties and strengthening human strengths—and in consequence reducing medical error and its consequences—is by acknowledging human factors as a part of human performance and thus acknowledging human limitation. The World Health Organization (WHO) states:

> *"A failure to apply human factors principles is a key aspect of most adverse events in health care. Therefore, all health-care workers need to have a basic understanding of human factors principles. Health-care workers who do not understand the basics of human factors are like infection control professionals not knowing about microbiology." (p. 111)*[196]

HUMAN FACTORS ON THE INDIVIDUAL LEVEL

This section will introduce three levels of human factors in more detail: (1) understanding the behavior of individuals (individual level), (2) the interactions between individuals (team level), and (3) their interactions with the organization (organizational level). This first section on the individual level addresses five interrelated elements: (1a) task management, (1b) situation awareness, (1c) decision making, (1d) general individual performance-shaping factors (e.g., fatigue, distractions and noise), and (1e) personal (safety) attitudes.

Task Management

According to the ANTS framework, task management is defined as (p. 8) "*skills for organizing resources and required activities to achieve goals, be they individual case plans or longer-term scheduling issues. It has four skill elements: planning and preparing; prioritizing; providing and maintaining standards; identifying and utilizing resources.*"[170]

Anesthesia professionals are often—within the operating room setting—their own phlebotomist, IV inserter, echocardiographer, pharmacist, technician, cleaner, data recorder, patient transporter, as well as performer of activities on behalf of the surgeon (e.g., manipulate the OR table, answer telephone calls, etc.) all while maintaining situation awareness, engaging in decision making, doing administrative tasks, and managing the anesthetic itself. That's a lot of activities! Task management in a team might include the delegation of tasks to appropriate personnel, using effective communication, and closing the loop, both to verify the request was received and understood and then to inform the leader that the task is done, or that there are problems.

Task density can become so high that (1) errors in tasks or their subtasks are more likely; (2) no single person can manage all the tasks alone[89] so that help from team members is needed (teamwork); and (3) tasks may be delayed by interruptions or competing demands, which then require prospective memory[130-134,197] to remember what to do in the future or to correctly resume interrupted actions.

Multitasking and Multiplexing. Sometimes multitasking—doing several things at a time—can be successful, depending on the situation and the tasks at hand. Yet professionals need to be aware that it can be unsuccessful when the situation or the tasks change. When task density becomes high, simple linear performance of tasks becomes impossible; instead more complicated processes of both multitasking and multiplexing are needed. Multitasking—trying to perform two (or more) tasks simultaneously—is frequent in hospital settings,[198] but is virtually impossible to execute if the same cognitive resources are involved. Conducting two or more relatively simple tasks is often possible, such as observing the surgical field while asking the surgeon a straightforward question. Even then there is a risk that one task will be dropped or degraded. However, adjusting an infusion pump while calculating the upcoming dose of antibiotic for an infant would be difficult to do in parallel.

In common use, the term multitasking sometimes refers specifically to media multitasking—everyday attempts to simultaneously work, listen to music, check email and text messages, and search the web. Studies[199,200] have shown that frequent media multitaskers perform worse on psychology laboratory probes of actual multitasking than those who are infrequent media multitaskers. Many suggest that true multitasking is impossible and that almost always there is a decrement of performance on some or all tasks when multitasking is attempted.

The degree to which media multitasking, or laboratory tests, relate to the kinds of multitasking performed by personnel in professional settings of many data streams and many tasks is as yet uncertain; it seems likely that in anesthesia care there are limits to what individuals can safely do on their own.

While simple multitasking in perioperative settings may work, when tasks are complex it may in fact be inefficient. Rather than conducting two (or more) activities in parallel, humans often do things sequentially but shift rapidly between items or back and forth across many simultaneous threads. If the tasks use different cognitive resources, this is referred to as multiplexing.[201] Multiplexing brings the challenges that people (1) have to refocus their concentration each time they switch and (2) are more susceptible to distractions and errors. This is especially true if the tasks at hand involve intensive real-time control as opposed to being cognitively automatic.[201] There is evidence that health care personnel are not aware of the risks of decreased performance when attempting to multitask.[202]

Douglas and co-authors recently reviewed the current literature concerning multitasking in the health care setting.[198] They suggest that multitasking typically results in increased time of task completion, increased stress, risk of memory lapses, and subsequent errors and accidents. Those performance limitations occur more often if one is forced to multitask by the environment and/or if the different tasks compete for the same local cognitive resource. Their review located only two studies on the association between multitasking and errors in the health care setting although nothing definitive was found. Executing two tasks at the same time was found to carry the risk of decreased accuracy and efficiency[203] and to have an increased reaction time to environmental stimuli.[204]

PATIENT SAFETY ACTION BOX

Keep focused. Instead of trying to do several things at once—and maybe none of them well—shift your attention consciously and completely from one task to the next and organize the tasks at hand according to priority. Giving your full attention to what you are doing will help you do it better, with fewer mistakes and less load on your prospective memory. Prevent or modulate avoidable distractions whenever possible.

Multitasking During Handovers?. One study observed different modes of patient handover from the OR to the postanesthesia recovery unit in six hospitals.[205] The researchers compared handovers of (1) *simultaneous* transfer of equipment and information (i.e., a nurse connecting the monitor while at the same time receiving verbal information) to (2) *sequential* transfer (equipment is first connected and lines sorted, then verbal information follows). The findings from 101 observed handovers showed that 65% of them took place simultaneously. Interestingly, simultaneous handovers were not significantly faster than sequential ones (1.8 vs. 2.0 min). In review of postoperative handovers Segall and colleagues[206] recommended: (1) standardize/structure processes (e.g., through the use of checklists and protocols); (2) complete urgent clinical tasks before the information transfer; (3) allow only patient-specific discussions during verbal handovers; (4) require that all relevant team members be present; and (5) provide training in team skills and communication. More information on handoffs is given in the later section on "Communication."

PATIENT SAFETY ACTION BOX

The recommendations given above are helpful for safe postoperative handovers. Another handover type occurs when one anesthesia professional replaces another, temporarily or permanently. And yet another handover is when you have called someone for help or when you are the one coming to help. For this last situation often the person arriving to help concentrates immediately on performing tasks without really listening to the briefing from the original anesthesia professional. Unless the task is critical (e.g., CPR) it is better to wait, assess the situation and the observable information, and then pay full attention to the briefing. For further information on handoffs see section "Effective Communication and Delegation of Tasks."

Situation Awareness

In anesthesia many sources of information need to be scanned in order to get the overview of the situation. These include, but are not limited to: the patient (clinical impression and history), various monitoring equipment, the patient chart, explicit and implicit information by colleagues and OR team members, and workday characteristics (i.e., staff composition, staff shortage, available equipment/time, etc.). Gaba, Howard, and Small introduced the concept of SA in the context of anesthesia in 1995.[110] Schulz and colleagues wrote a review article in 2013 especially on SA in anesthesia. [135]

Situation awareness (SA) describes *"the ability of an individual to maintain an adequate internal representation of the status of the environment in complex and dynamic domains where time constants are short and conditions may change within seconds and minutes"* (p. 729). [135]

SA is a concept drawn from military aviation concerning a variety of aspects of cognition in complex real-time environments. While important itself, situation awareness is influenced by previous decisions, communication patterns, and team dynamics; the level of SA in turn influences team communication and coordination. Situation awareness incorporates the circumstances of the patient at hand (e.g., "Is all required expertise represented?"), the state of the treatment team (e.g., "Is a team member task-overloaded?," "Do team members trust each other?"); and the state of the environment including the rest of the facility (e.g., "Is the problem I'm having also happening elsewhere in my OR suite?").

One of the primary experts on SA, Mica Endsley,[207-209] postulates three different components of individual SA: (1) *Perception* of the elements of a situation/environment within a volume of time and space (= gathering information, detection of cues); (2) *comprehension* of elements and their meaning (= interpretation of information/cues, diagnosis); and (3) *projection* of their status in the near future (= anticipation, prediction). Dekker and Hollnagel challenge this model.[210,211]

Success or failure of SA can occur at each component: gathering, comprehension, and projecting. Some readily available information can be missed, or perceived incorrectly; on the other hand experience makes them sensitive to barely perceptible cues. They also often, but not always, comprehend the meaning of what is perceived by everyone even when others miss its significance.[212] Experts also are usually able to assess the situation not only as it stands but also to project where things are headed, but of course their future projection can be inaccurate or disregarded (including the "everything is OK fixation error").

Schulz and colleagues reviewed 200 incidents in anesthesia and critical care in an in-hospital setting and determined the frequency of situation awareness errors for an individual patient.[136] Admittedly there could be some degree of hindsight bias; nonetheless, situation awareness errors were identified in 81.5% of cases—predominantly in perception (38.0%) and comprehension (31.5%).

Shared Situation Awareness. SA is a concept that can be applied to the individual (personal SA, see above), but also the team (shared SA). Team SA is defined as *"the degree to which every team member possesses the SA required for his or her responsibilities"* (p. 39).[207] Within different professions and different physical positions in the room, the situational awareness and interpretation of the same case can differ substantially within a team, due to variation in experience, involvement, focus point, interest, knowledge, or information. Of course, not every bit of information can be shared with the whole team; doing so would overwhelm everyone. Yet, creating and maintaining an overall shared mental model of the situation across all team members is critical for determining the best plan of action for patient care. Some team communication in the operating room that seemingly does not serve an obvious purpose, might, in fact, be a gauging of shared mental models and therefore shared SA.[213,214] Anesthesia professionals, for example, routinely assess the progress and possible complications of the operation by perceiving nuances in the conversation of the surgeons.[213]

Shared mental models predict good team performance[215] and were, for example, shown to be related to positive performance in trauma teams, with team leaders and followers actively working toward an information exchange.[216] Adapted from psychology and management literature, Schmutz and Eppich[217] introduced the conceptual framework of team reflexivity to health care. They propose that shared SA is fostered by components of team reflexivity, namely (1) pre-action briefing, (2) in-action deliberation, and (3) post-action debriefing. Fioratou and colleagues[218] challenge the common model of individual and team SA and instead introduced the model of distributed situation awareness (DSA) to anesthesia, arguing that cognition actually involves elements of the (physical) environment, for example, the values on a monitor.

A multicenter study from Denmark explored shared mental models of surgical teams during 64 video-assisted thoracoscopic surgery lobectomies to explore familiarity of the people involved in the operation with each other; mutual assessment of technical and nontechnical skills in the other persons present during the operation; assessment of the perceived risk for the patient from the procedure and from the anesthetic; and noting of problems in the present co-works task management. There was poor agreement between team members' risk ratings showing limitations in how much the members of the surgical team share a mental model about the patient and the related risks. A follow-up study demonstrated the connection between relevant clinical markers and shared mental models.

Other aspects of situation awareness have already been introduced within the "core cognitive process model" in an earlier section. Box 6.2 gives examples of reevaluation questions in order to maintain situation awareness.

Decision Making

Decision making is the generic term for the cognitive and emotional processes of determining appropriate information seeking and actions in a changing environment. It involves "*skills for reaching a judgement to select a course of* *action or make a diagnosis about a situation, in both normal conditions and in time-pressured crisis situations. It … [includes]: identifying options; balancing risks and selecting options [and] re-evaluating"* (p. 13).[170] Many aspects of the anesthesia professional's decision making have already been addressed in the earlier section where the "core cognitive process model" was introduced, so for more information the reader is referred back to that section.

Although decision making in anesthesiology involves many sorts of perioperative decisions, this chapter is particularly interested in the processes used for the non-routine decisions made during the management of problems or crises. This is a very complex process. Although information is sometimes used in what seems to be a purely rational manner,[219,220] decision making is affected strongly by a number of non-rational elements such as group pressure, ingrained habits, cognitive biases, and perceptual illusions. When determining the alternatives and their various pros and cons the set of options available or their perceived value will also vary.

Traditional concepts of decision making in much of medicine (not anesthesiology) have concentrated on relatively static, well-structured decisions. For example, should patient A with an elevated blood pressure be treated for hypertension with drug X, or should no treatment be started? Other studies have looked at diagnosis as an isolated task (specifically, diagnostic explanation) both in internal medicine and in radiology. These approaches to decision making have not captured the unique aspects of dynamism, time pressure, and uncertainty seen in anesthesiology. Since the 1980s, several paradigms have emerged regarding decision making and action in complex real-world situations.

On the one hand there are models that have their basis largely in research done in the psychology laboratory investigating the limits and pitfalls of decision making under controlled conditions, especially delineating cognitive biases. Daniel Kahneman and his colleague Amos Tversky won a Nobel Prize in Economics in 2002 for this kind of research. While Tversky passed away in 1999 Kahneman continued to work on decision making, and he recently synthesized and summarized the topic in the popular book *Thinking Fast and Slow*.[212] Two cognitive systems are described. System I is intuitive (heuristic), very fast, less concerned with the precision of the information processing and decision (as long as it is approximately correct) and more concerned with reducing cognitive load. Research about heuristic decision making shows that reducing the amount of information considered can still lead to equally good or superior decisions.[221] System II is analytical, slow but able to consider in detail the sources of information and the fine points of a decision. Especially in time-critical situations humans tend to run on System I as long as possible, sometimes too long—accepting imprecise results when precision is actually needed. Understanding the pitfalls of System I thinking can help professionals to lower the bar for their activation of System II. Another approach to studying and describing decision making, based on observational research on professionals engaged in doing complex decision-making work in real-world settings (or simulations thereof) is known as naturalistic decision making (NDM), with Gary Klein, Judith Orasanu, and others as the pioneers.[45,114,118] Models in NDM-oriented work also invoke the idea of parallel systems of decision making, one heuristic and fast, the other systematic, precise, and slow, as well as a number of other aspects of iterative consideration of useful actions.

The core cognitive process model including dynamic decision making (see earlier section on "Core Cognitive Process Model of the Anesthesia Professional") is based largely on the NDM model, but is consistent with Kahneman's description of System I and System II. In fact, Klein and Kahnemann have co-written a paper that outlines how their two approaches are in many ways similar, while in a few ways somewhat different. [222] A common (if incomplete) way to describe this is that the work of Kahneman and Tversky emphasizes the pitfalls and errors of decision making, NDM emphasizes how it is often successful despite these risks.

Stiegler and Tung—representing views influenced by the Kahneman-Tversky research—(1) identified current theories of human decision behavior in the context of anesthesia, which are: expected utility, Bayesian probability, formalized pattern matching, heuristics, dual process reasoning, and sensemaking; (2) identified common effects of non-rational cognitive processes on decision making; and (3) suggested strategies to improve anesthesia decision making.[121]

In another publication, Stiegler and co-workers summarized the most common cognitive/non-rational errors detected specific to anesthesiology practice; the leading 10 errors were anchoring, availability bias, premature closure, feedback bias, framing effect, confirmation bias, omission bias, commission bias, overconfidence, and sunk costs.[61] In a simulated emergency setting, the frequency of seven of those errors was over 50%, with premature closure (accepting a diagnosis prematurely, failure to consider reasonable differential of possibilities) and confirmation bias (seeking or acknowledging only information that confirms the desired or suspected diagnosis) being the most common cognitive errors with a frequency of nearly 80% each. In 2016 the Joint Commission also published a paper on the safety issues of cognitive errors and factors that can predispose or increase the likelihood of cognitive biases.[62]

Gigerenzer frames the view on the characteristics of human decision making differently.[223,224] What is called biases in other frameworks is seen as relevant features of human cognition and decision making that allow for functional perception and action in a very complicated world. Perhaps like NDM, this view suggests that theories of decision making do not really describe decision making in the real world. For example, in many situations it will not be possible to collect all relevant decision alternatives, to assess them fully, and to select the best option. There might not be enough data available about the alternatives and/or the evaluation might take too long. The "take-the-best" (also termed "satisficing") heuristic suggests that decision makers consider what they see as a key feature for the decision and only compare any alternatives along this criterion. Further criteria are only considered if the first ones do not identify an acceptable option.

PERFORMANCE-SHAPING FACTORS ON THE INDIVIDUAL LEVEL

The previous discussion about the performance of skilled anesthesia professionals has mostly assumed that they are normally fit, rested, and acting in a standard working environment. However, human performance on the individual level also depends on so-called performance-shaping factors such as interruptions, distractions, fatigue, and stress. Performance-shaping factors can predispose a person to error. Experience in human performance in the laboratory and other domains suggests that internal and external performance-shaping factors exert profound effects on the ability of even highly trained personnel. The degree to which this occurs and to which it affects patient outcome is highly uncertain. In extreme cases, such as profound fatigue, it is obvious these factors result in severe degradation of the anesthesia professional's performance or even complete incapacitation. However, these extreme conditions are quite unusual, and it is still unclear whether the levels of performance decrement most frequently seen in typical work situations have any significant effects.

Several performance-shaping factors are potentially of sufficient magnitude to be of concern. Those include ambient noise, music, distraction by personal electronic devices, distraction by other personnel, fatigue and sleep deprivation, aging, illness, drug use, and relatively fixed hazardous attitudes. These are discussed in the course of this section. A variety of other performance-shaping issues such as the level of illumination and environmental temperature are not dealt with in this chapter.

Currently, the responsibility for ensuring fitness for duty rests solely with the individual clinician. In high-reliability organizations (see later), where the maintenance of organizational safety is one of the key elements, the institution implements measures to mitigate decrements due to performance-shaping factors. As health care systems address issues of human performance and patient safety more seriously, these aspects of work will need to be dealt with.

Distractions and Interruptions in the Operating Room

Several recent publications deal with distractions and interruptions in the OR. For detailed information the reader is referred to further literature,[68,95,96,225-234] as the upcoming section can only give a brief overview on the topic.

Ambient Noise and Music. The workplace of anesthesia professionals—predominantly, but not exclusively, the operating room—is a very complex physical and cognitive setting. Unless there is an unusual effort to reduce sound levels the routine noises of the suction, surgical equipment (electrocautery, pneumatic or electric power tools), and monitoring equipment yield levels considerably higher than in most offices or control rooms. Other sound sources such as conversation and music are controllable. The potential interference of noise with communication and situation awareness[235] among personnel in the OR is particularly worrisome to those concerned with optimizing teamwork in this complex work environment.[68,236]

The use of music in the OR is now widespread. Many health care professionals believe that music enlivens the workday and can build team cohesiveness when all team members enjoy the music. Others note that in some cases the volume level of music makes it harder to hear the rhythm and tone of the pulse oximeter and alarms as well as work-related conversation between team members. A laboratory study by Stevenson and colleagues determined that visual attentional loads and auditory distractions additively reduced anesthesiology residents' ability to detect changes in pulse oximeter tone.[235]

A controversial study by two social psychologists, Allen and Blascovich, suggested that surgeon-selected music improved surgeons' performance on a serial subtraction task and reduced their autonomic reactivity (i.e., "relaxed" them) when compared with control conditions consisting of experimenter-selected music or no music at all.[237] The methodology of this study has been criticized.[238] In response to Allen and Blascovich, several anesthesiologists challenged the notion that the surgeon's preference for the type or volume of music can or should override the needs of other members of the team.[238]

Murthy and colleagues[239] studied the effect of OR noise (80 to 85 dB) and music on knot-tying ability in a laparoscopic skill simulator. They found no difference in time or knot quality in the conditions tested and concluded that surgeons can effectively block out noise and music. The invited commentary that accompanied the article brings up important issues: What impact does noise have on other members of the surgical team? How does noise affect communication between team members? Does noise affect judgment? The question of the proper role of music in the OR has no simple answer. Clearly, optimal patient care is the primary goal. Some surgical or anesthesia personnel explicitly forbid any type of music in the OR. A more common approach of many OR teams is to allow any team member to veto the choice or volume of music if they believe that it interferes with their work.

PATIENT SAFETY ACTION BOX

Distractions include music, social conversation, and jokes. Each of these activities is appropriate under the right circumstances. They can make the work environment more pleasant and promote the development of team spirit, but they can also seriously lessen your ability to detect and correct problems. This issue can be raised during the presurgical time-out to ensure that all personnel agree. During patient care you must take charge of modulating these activities so that they do not become distracting. If the music is too loud, one must insist that the volume be reduced or that it be turned off (a rule of thumb is that the pulse oximeter volume should always be louder than the music or conversation). When a crisis occurs, all distractions should be eliminated or reduced as much as possible.

Reading and Use of Mobile Electronic Devices. The observation that some anesthesia professionals have been seen to read journals or books casually during patient care led to a vigorous debate of the appropriateness of such activity.[240] Although it is indisputable that reading could distract attention from patient care, a study by Slagle and Weinger in 2009 suggested that when the practice of reading is confined to low-workload portions of a case, it has no effect on vigilance.[65] Many comments about the issue were related not to the actual decrement in vigilance induced by reading but rather to the impact of the negative perception of the practice and of those who do it by surgeons and by patients, if they were aware of it.

This issue has been greatly magnified by now-ubiquitous smartphones and social media. Nearly all clinical personnel (other than those scrubbed into surgery) have a smartphone immediately at hand. These provide great temptation for both pull activities—reading email, websites, or social media sites—and push activities, notification of new text messages, mail, or social media posts. The wide variety of channels of information makes it far more likely for people to spend time interacting with their phones than with newspapers, journals, or books. The content available is never ending. In their survey, Soto and colleagues give a current update of the usage patterns, risks, and benefits of personal electronic device use in the operating room.[241]

Distractions Caused by Work Itself. An important source of distraction is actually the work itself. That is, engaging in one task can distract attention from other important tasks. Repositioning the patient on the operating table (or rotating the table itself) can take a surprising amount of time and physical and mental effort. During these tasks it can be difficult, and in some cases impossible, to maintain all usual data streams, or to view, hear, or attend to them. Another highly distracting activity is the use of echocardiography, which requires focused attention on the image and manipulation of the probe and of the device's interface. While it may generate crucial clinical information, it can also distract attention from other important monitors or the surgical field.

Interruptions. Beyond distracting attention from important data streams, various stimuli can also cause "interruptions" in the sequence of conducting a task.[95] Campbell and associates[96] found that slightly more than 20% of distractions—particularly interruptions—were associated with an observable negative impact. Such events are particularly problematic when they disrupt prospective memory which is one's ability to *remember in the future* to perform an action or to resume interrupted tasks in the right spot.[132] It is particularly prone to disruption by concurrent tasks or interruptions. In anesthesia, for example, if the anesthesia professional suspends ventilation temporarily (say to allow a radiograph to be taken), the intention to restart the ventilator depends on prospective memory and can be easily forgotten.

A variety of methods may preserve prospective memory of intentions. Visual or auditory reminders can be used (physiologic monitor alarms often serve this purpose whether intended or not), although the effectiveness of such methods is variable.

PATIENT SAFETY ACTION BOX

Special actions—such as leaving one's finger on the ventilator switch when one has turned off the ventilator for an appropriate reason—can be used to indicate that an important intention is pending. Another strategy is putting a small sign on the ventilator to remind you that it is off. As a last resort in this example, properly set alarms should warn you of apnea should you forget to turn the ventilator back on. Depending on the requested action another strategy can be to accustom oneself to consciously finish tasks entirely before starting the next task (see also section on Task Management). If team members interrupt during a task it can be helpful to let them know that you are busy, something like "One moment please, you'll have my full attention shortly." However, asking others to help you remember ("can you please remind me"), has shown to be a less effective strategy, apparently because it diffuses the responsibility to actually remember.

Resulting Implications. Clearly, for all these distractions and interruptions the pros and cons of policing them need to be balanced. In our opinion—similar to those of Slagle and Weinger[65]—blanket policies against reading nonessential materials or interacting with mobile phones except for patient care needs are both doomed to failure and possibly detrimental. First, because they are hard to enforce and any intensive efforts to eradicate the use of such devices at work is likely to generate a tense work climate despite the best safety intentions of proponents. Second, because reading or phone use might actually counteract boredom in some situations and thus might increase performance. Third, these distractions are not necessarily any different from many other kinds of activities not related to patient care that are routinely accepted, such as social conversation among personnel. Of course, there are reasonable limits for such activities.

The bottom line is, to quote Slagle and Weinger: "*(1) the patient must be the foremost priority and (2) being distracted or performing noncritical tasks during critical or unstable situations is inappropriate and dangerous*" (p. 282).[65] In the end it is important for anesthesia professionals to keep in mind that there are potential pitfalls linked to distractions and that the anesthesia professional is responsible for modulating controllable distractions and for developing work processes that balance the cognitive load of tasks against their personal, clinical, or teambuilding utility. Allowing music during routine work (if all agree) and a modest amount of reading or smartphone use, but emphasizing the need to reduce or eliminate it when it is too distracting, the workload increases, or a situation becomes complex or urgent is one example. The threshold for abandoning any potential distraction to provide maximum attention to patient care should be rather low.

In response to the patient safety concerns related to distractions and interruptions in the OR and other patient care areas from the use of personal electronic devices for non-patient-related purposes, several professional societies and organizations have established position statements and guidelines to define appropriate use of those devices in the OR.[242-245] Some health care settings have implemented a "no interruption zone"[242,246] during critical phases of patient care activities, in the style of a "sterile cockpit" concept,[100] derived from aviation regulations that prohibit crewmembers from engaging in any activity except those duties required for the safe operation of the aircraft during critical phases of flight.

Stress. Stress is a performance-shaping factor that influences human performance. To go into detail about stress is beyond the scope of this chapter. Therefore the reader is referred to other references for more details.[11,247]

Sleep Deprivation and Fatigue

Fatigue is common in the life of anesthesia professionals, whether due to work hours, on-call duties, or the vagaries of life with children and otherwise. Sleep can be thought of as a physiologic drive state similar to hunger or thirst and is necessary for maintenance of alertness, performance, and overall well-being. The amount of sleep required by any individual is genetically determined and is the amount that allows that individual to be awake and alert throughout the day. The average sleep time for young adults is 7 to 8 hours per 24-hour period, with an approximately 15% interindividual variation. These sleep requirements do not change with age, and humans can do little to train their physiology to function optimally on less sleep than required.

The physiology and psychology of sleep and sleep deprivation are well established, and this section can only provide a cursory summary of what is known.

Sleep Debt. Sleep loss is cumulative and results in what is referred to as sleep debt. An individual who has obtained an optimal amount of sleep is better prepared to perform long periods of sustained work than one who is operating from a sleep debt. Because of the additive effects of chronic partial sleep loss, even minor sleep restriction on a nightly basis can insidiously accumulate into a substantial sleep debt. The only way to pay back a sleep debt is with sleep. Sleep debts are commonplace in our culture. The National Sleep Foundation's annual survey continues to reveal that Americans chronically undersleep by 30 to 90 minutes each day.[248] Shift work, long and irregular work hours, and the demands of family and recreation lead to irregular sleep patterns and prevent restful sleep. This is particularly true for health care workers, who often work in shifts, have long duty periods, and must frequently care for patients for long periods. To some degree it seems as if sleep deprivation might have led into a situation that is more dangerous than one thinks.

Circadian Rhythms. Our biological clock, responsible for the human circadian system, is synchronized to the 24-hour day by external stimuli referred to as "zeitgebers," the most influential of which is the light-dark cycle of day and night. The circadian system is biphasic in that it produces a state of increased sleep tendency and decreased performance capacity during two periods throughout the 24-hour day—from 2 a.m. to 6 a.m. and from 2 p.m. to 6 p.m. These are periods when professionals are more vulnerable to incidents and accidents because the body clock is "turned off." The circadian clock is very resistant to alterations, and it does not adjust rapidly to changes such as those produced by jet lag or shift work. Disruption of the normal circadian rhythm or incomplete circadian adaptation leads to acute and chronic sleep deprivation, decreased alertness, increased subjective fatigue, and decreased physical and mental performance.[249]

Sleepiness and Alertness. Sleepiness and alertness are at opposite ends of a continuum. Daytime sleepiness is the most obvious effect of failing to obtain adequate sleep. Data from the U.S. Department of Transportation reveal that the greatest number of single-vehicle accidents takes place during the early morning hours when people are at a circadian lull of alertness. These accidents are thought to result from inadvertent lapses in driver attention brought about by extremes of sleepiness.[250]

Both behavioral and subjective sleepiness can be masked by a stimulating environment. When environmental stimuli wane, physiologic sleepiness manifests itself as an overwhelming propensity to fall asleep. A person who is physiologically alert does not experience sleepiness as environmental stimuli decrease. For example, without physiologic sleepiness, an individual may become bored during a lecture but does not fall asleep.

Microsleep Events. The most extreme cause of impaired vigilance is the occurrence of actual sleep episodes (microsleeps) encroaching into periods of wakefulness. Microsleep events typically last a few seconds to a few minutes. They are intermittent in onset, and their impending occurrence is difficult for the individual to predict. Most individuals underestimate their level of sleepiness when they can be objectively shown to be extremely sleepy, thus making this problem even more insidious. This has significant meaning in the workplace and when driving home after long work periods.

Microsleeps are a sign of extreme sleepiness and are harbingers of the onset of longer sleep periods. Typically, they occur during periods of low workload or stimulation and when an individual is maximally sleepy. In addition, an individual's performance between microsleep episodes is impaired. Frequent and longer microsleeps increase the number of errors of omission.

Evaluation of Physiologic Sleepiness in Anesthesia Residents. Using the Multiple Sleep Latency Test (MSLT), a sleep disorder diagnostic tool, Howard and colleagues evaluated the physiologic (objective) daytime sleepiness of anesthesia residents under three different conditions: (1) baseline (daytime shift, no on-call duty period in the previous 48 hours), (2) post-call (immediately after a 24-hour work and in-house on-call period), and (3) sleep extended.[251,252] In the sleep-extended condition, residents were told to maximize sleep and were allowed to arrive for work at 10 am (3 to 4 hours later than normal) for 4 consecutive days before testing. They were not on call during this time. The sleep-extended condition was included to provide a true control state of maximal rest and optimum alertness. In this study, for anesthesia residents the MSLT scores for baseline as well as for post-call condition revealed the nearly pathologic levels of daytime sleepiness seen in patients with narcolepsy or sleep apnea. The baseline group slept an average of 7.1 ± 1.5 hours per night, whereas the post-call group reported an average of 6.3 ± 1.9 hours of sleep during their night on call. Ironically, although the on-call periods occurred during rotations that often have very busy call nights, only a few subjects were, in fact, awake most of the night. In the sleep-extended condition, the subjects extended their sleep to an average of more than 9 hours per night, and MSLT scores were in the normal range. These results clearly demonstrate that medical personnel who have not been on call cannot be assumed to be rested when compared with fatigued post-call residents. These data also indicate that under normal working conditions, the resident physicians studied were physiologically sleepy to nearly pathologic levels. Notably, these data cast substantial doubt on previous studies of the performance of medical personnel that have relied on the assumption that individuals working under normal conditions are truly rested.

Evaluation of Subjective Sleepiness in Anesthesia Residents. The previously mentioned study also investigated the connection between subjective and physiologic sleepiness. In the previously discussed study, Howard and colleagues also investigated the degree of discrepancy between the residents' subjective sleepiness (how sleepy they felt) and their physiologic sleepiness (how easily they fell asleep). Subjects' self-reported sleepiness immediately before each sleep opportunity did not, in general, correlate with their measured sleepiness. The authors also found that subjects demonstrated little ability to determine whether they had actually fallen asleep. For example, in 51% of trials in which the electroencephalographic and electro-oculographic measurements showed that the subject had fallen asleep, the subjects thought they had remained awake throughout the test. These results support the contention that medical personnel are physiologically vulnerable to degraded alertness yet are unable to perceive this decrement. Thus, an anesthesia professional could, in fact, fall asleep during a case, awaken, and be totally unaware of the lapse in vigilance.

Mood. Long work hours, fatigue, and sleep deprivation have been shown to bring about consistent and dramatic changes in mood and emotions. Depression, anxiety, irritability, anger, and depersonalization have all been shown to increase during testing of chronically fatigued house staff. These emotions are an obvious source of stress between anesthesia professionals and their co-workers, patients, and families. The relationship of mood, performance, and patient safety has yet to be determined.

Sleep Inertia. Sleep inertia corresponds to the period of reduced ability to function optimally immediately on awakening. This phenomenon usually occurs when individuals are awakened out of slow-wave sleep and is manifested as grogginess and impaired performance lasting as long as 15 to 30 minutes after awakening. Sleep inertia can also occur after being awakened from normal sleep and is most common during the early morning circadian trough (2 to 6 am). Depending on the preexisting level of sleepiness, individuals who take naps longer than 40 minutes are at greater risk for sleep inertia on awakening.

PATIENT SAFETY ACTION BOX

Sleep inertia can be important to health care professionals who may be awakened out of deep sleep to provide emergency care to patients (e.g., emergency cesarean section or emergency intubation). If urgent work can be anticipated, the sleeping individual should be awakened with sufficient time (at least 15 minutes) to minimize the fogginess and decrement in performance associated with sleep inertia. Another option is to not sleep longer than short naps in situations where immediate performance is required. If sleep inertia is unavoidable, it would be wise for the affected person to ask for help until the grogginess dissipates.

Effects of Fatigue on Anesthesiologists' Performance and Patient Outcome. It is highly uncertain as to whether, how, or in what circumstances these established psychophysical changes might interact with clinical work processes to affect patient safety in anesthesiology. Various methods are used for assessing an individual's level of sleepiness, including behavioral indicators, subjective measures, and physiologic (objective) measures.

The survey by Gaba and associates revealed that more than 50% of respondents believed that they had made an error in clinical management that they thought was related to fatigue.[56] In another survey of anesthesiologists and CRNAs, 61% of respondents recalled having made an error in the administration of anesthesia that they attributed to fatigue. In a study in 2011, a large, national, random sample of CRNAs in the United States was asked to complete an anonymous survey to quantify sleep activity.[253] Findings of the almost 1300 respondents revealed that nearly 16% have experienced sleep-related behavior during a surgical case, and close to 50% have witnessed a colleague asleep during a case. A similar survey of CRNAs was conducted in 2015, where nearly 30% of the 325 respondents reported they had committed a patient care error because of fatigue.[254]

The challenge of sleep deprivation and fatigue in medical personnel was addressed by the Joint Commission on Accreditation of Healthcare Organizations in 2011 in a Sentinel Event Alert on "Health Care Worker Fatigue and Patient Safety."[255] The Sentinel Event Alert is public and can be retrieved from the homepage of the Joint Commission. Sinha and co-workers ask: *"The fatigued anesthesiologist: A threat to patient safety?"*[256] and Gregory and Edsell picked up the topic in their educational publication in 2014. [257]

Considerable research on fatigue effects has targeted the transportation industries, especially driving which needs both continuous vigilance and psychomotor skill. If a driver has microsleeps lasting many seconds a problem is likely, unless the road is quite straight or there is an autosteering/autospeed autonomy. Even in health care, studies have largely been carried out in hospital ward settings where, during night on-call shifts, they may have responsibility for many patients.[258] The anesthesiology environment is different. Each patient having anesthesia will have at least one anesthesia professional in constant attendance and that individual is not directly responsible for other patients at the same time. Moreover, although vigilance is indeed the slogan of the ASA, there are few situations that require sustained second-by-second attention. The demand for high vigilance and effort does not usually occur at random; such situations are usually present at induction, emergence, and a few key milestones during the surgical procedure. Critical events are uncommon, and even when the chain of accident evolution has begun, the clinical team will likely have multiple opportunities to detect and correct it before any substantive negative impact has occurred. Thus, while anesthesia personnel may be prone to fatigue, and complaints about sleepiness and fatigue are common, the probability of a negative patient outcome during anesthesia directly attributable to sleepiness alone is very small. In health care, there is no formal mechanism for evaluating causation in adverse events, let alone for evaluating sleep-wake issues and fatigue, so one does not know the full contribution of this factor to negative outcomes. As for many aspects of human performance, variables that can be reliably and precisely measured do not capture the complexity or the typical resilience of clinical work. Conversely, measures and techniques that do address such factors are by nature non-quantitative and invasive.

Howard and colleagues conducted a study of rested versus sleep-deprived (awake for 25 hours on a pseudo-on-call period) anesthesiology residents by collecting multiple measures of performance during a 4-hour high-fidelity simulation scenario: Mood questionnaire, PVT psychomotor reaction time, response time to secondary task probes, and response to changing clinical events.[78] Psychomotor tests revealed progressive impairment of alertness, mood, and performance over the course of the pseudo–on-call period, as well as on the experimental day, when compared with the well-rested condition. Secondary task probe response times were slower after sleep deprivation, although this reached statistical significance for just one of three probe types. No statistical difference in case management between conditions was reported—in fact, subjects in both conditions made significant errors. Sleep-deprived subjects cycled (often rapidly) in and out of sleepy behavior, and the most impaired individuals showed such behavior for more than 25% of the experiment (60 minutes).

A key thing learned about fatigue during this study[78] was that highly fatigued anesthesia personnel in simulations are not either awake all the time or asleep all the time. Rather they usually cycled frequently in and out of states of apparent wakefulness, drowsiness, and microsleeps throughout the simulated case. Typically, when awake their performance was at most mildly degraded but when they showed extreme drowsiness or were actually asleep their performance was essentially zero. Participants were observed being totally asleep at one moment but awakening just in time to happen to catch a probe stimulus or clinical event, and respond to it satisfactorily. For most subjects the fraction of time spent in highly impaired states was low as their microsleeps were brief, in part because even a quiet routine clinical setting has a variety of stimuli, including other personnel and their tasks. The intrinsic redundancies in the OR team, the potential benefits of monitor alarms, and the resilience of clinical systems and patients may explain why catastrophes during anesthesia are very rare even though many operations are conducted with personnel suffering from substantial chronic and acute fatigue.

Fatigue Countermeasures. Anesthesia professionals cannot prevent sleepiness by willpower alone because it is a fundamental physiologic drive. Strategies that institutions or practitioners can use to minimize the negative effects of sleepiness and fatigue on performance include: education and promotion of safety culture, improved sleep habits, rest breaks at work, strategic napping, medications and social drugs, and light therapy. Strategies that national bodies and professional societies and organizations can call for are reasonable duty hour requirements.

Duty Hour Requirements. One direct regulatory strategy to minimize sleep deprivation has been to limit the work hours of clinicians. For the most part this has been attempted only for those in training (who traditionally have worked very long hours both during the day and in nighttime on-call). Results of process and outcome studies have varied but there has been no proof that such regulations, by themselves, improve patient safety.[259] Changing work schedules will not eliminate chronic fatigue, and in settings where clinicians at night may cover large numbers of unfamiliar patients the probability of information loss and confusion across the handoffs may outweigh any benefits of greater alertness. Yet, these findings may not apply to the anesthesiologists' operating room environment in the same way. The previous studies provided addressed the effects of sleep deprivation and fatigue on physician performance and well-being.

Back in 2003 the Accreditation Council for Graduate Medical Education (ACGME) instituted the first set of common duty hour requirements for all accredited residency training programs in the United States. Those requirements were revised in 2011[260] in response to the 2009 Institute of Medicine (IOM) report entitled *Resident Duty Hours: Enhancing Sleep, Supervision, and Safety.* A white paper published by Blum and colleagues debates the latest information and innovative practices on the topic and discusses how to best implement the 2009 IOM recommendations.[261] Work hour regulations in the European Union and in Australia or New Zealand are much more stringent than they are for trainees in the United States. For more details on work hour regulations see also further literature.[259,262,263]

Education and Safety Culture. A first and relatively simple and inexpensive step in addressing sleepiness and fatigue of medical personnel is to educate practitioners and the administrators of health care institutions about the impact of sleep issues on work performance, mood, job satisfaction, and health. Educational programs covering sleep deprivation, circadian disruption and fatigue, and countermeasures have been enthusiastically adopted by an increasing fraction of the aviation community. Similar programs should be developed for the health care community. However, it is clear at both the individual and organizational level that education will not be sufficient to address this issue fully. Other competing forces, for example measures of production versus safety, are very powerful and difficult for practitioners to manage.

The organizational framework plays a major role. Only if fatigue is seen as an organizational issue affecting safety negatively and safety is made a high organizational priority with all the resulting consequences, will fatigue-related safety issues be minimized. For an organization that implies, for example, that (a) tired staff are not always implicitly expected to work under all circumstances, (b) opportunities are created for tired staff to rest and to recover (i.e., regular rest breaks, strategic napping, etc.), and (c) an organizational safety culture is fostered that allows anesthesiologists to call for the assistance of a colleague (teamwork, speak up, see next section) when they know that they are impaired (from fatigue or for any other reason), without any negative consequences (cowardice, etc.). For additional countermeasures also see the Sentinel Event Alert of the Joint Commission[255] introduced earlier.

IMPROVED SLEEP HABITS. It is important to obtain adequate sleep. Most adults need at least 8 hours and the amount you need will not change—no matter what you do. Good sleep habits include the following: regularity of bedtime and wake-up time; sufficient time for sustained and individually adequate sleep; restriction of alcohol, caffeine, and nicotine before bedtime; and use of exercise, nutrition, and environmental factors so that they enhance rather than disturb sleep. Also, mobile devices should be put aside about half an hour before sleep—not only because of their (blue) light that signals "wake-up time" to the body, but also because a lot of what you read in them might get your heart-rate up, not down.

A regular sleep schedule is an important part of optimal sleep hygiene, but it is often not possible for medical personnel, given the requirement to cover clinical needs on a 24-hour basis. It helps to maintain as constant a sleep schedule as possible and to maximize sleep opportunities before and after periods of reduced sleep. Social drug use can have profound effects on sleep (see below). Ideally, the sleep setting should be a dark, quiet room devoid of sources of interruption such as pets, telephones, pagers, and children. Psychological stressors increase baseline physiologic arousal and can impair the quality and quantity of sleep. When possible, effort should be made to separate the work of the day with a period of relaxation before attempting to initiate sleep.

Caffeine and other stronger stimulants are known to reduce nocturnal sleep if ingested close to bedtime, hence decreasing sleep quantity and quality. Potent stimulants such as amphetamines do produce increased alertness and performance, but they have significant side effects and are not an option for health care personnel (e.g., the individual must undergo a substantial amount of recovery sleep ["crash"] after their effect is gone).

Rest Breaks, Strategic Napping at Work, and Use of Caffeine

REST BREAKS. Although other industries have openly recognized the reality of decrements in vigilance resulting from fatigue and sleepiness, the health care system has not. Rest breaks and rotation of task duties are mandatory for air traffic controllers and are part of naval ship command procedures in an attempt to prevent potential lapses in vigilance. Short breaks in surgery have been shown to increase productivity and job satisfaction, and they probably also help alleviate boredom.[264] The organizational hurdle in anesthesia: oftentimes an extra anesthesia professional would be necessary to provide these opportunities on a regular basis.

The optimal timing and length of breaks are unknown, but periodic relief from duty should be taken when possible. Cooper and co-workers studied the effects of intraoperative exchange of anesthesia personnel.[265,266] Although in some cases the process of relieving OR personnel caused a problem, it more frequently was associated with the discovery of a preexisting problem. The positive effect of relief of personnel probably depends on the quality of the handover briefing conducted by anesthesia professionals. If anesthesia professionals are unable to obtain a break during long work periods, they can take other measures to remain alert. They can engage other OR personnel in conversation (although this, too, can be distracting), thereby increasing the level of stimulation in the environment. Walking around and standing up are also techniques that decrease subjective (but not physiologic) sleepiness.

STRATEGIC NAPPING AT WORK. If adequate sleep during the night cannot be obtained, naps can be used to decrease sleepiness and improve performance. The optimal nap length for most individuals is about 45 minutes; this duration acutely improves alertness, allows improved performance, and minimizes the possibility of sleep inertia on awakening. Naps as short as 10 minutes have beneficial effects on alertness. A nap of 90 to 120 minutes allows a full sleep cycle and can additionally boost alertness and performance over that of shorter nap periods.

Health care professionals oftentimes have an individual and cultural tendency to ignore or to minimize the effect of fatigue and sleep deprivation and to view work breaks and naps as signs of weakness. The military has addressed similar attitudes with the concept of 10 minute power napping, presenting naps in a positive light as a sign of wisdom and strength rather than one of cowardice and frailty. Again, the predominant organizational safety culture is one of the key elements—how critical safety and quality issues like fatigue are judged and how those obstacles are met (see above and later sections on "Patient Safety at the Organizational Level").

Smith-Coggins and associates studied the effect of naps during the night shift on health care providers working in a busy suburban university emergency department.[267] The investigators found that a nap improved performance on some (but not all) measures. The most important result of this study may be the fact that the subjects were able to (1) use this strategy successfully in the real workplace and (2) improve alertness and performance. At some sites within the Veterans' Affairs system a strategic nap program has been successfully developed and implemented in ICU settings.[268] Components included a formal educational program, guidelines for the individual practitioner and the facility, and other guidance for implementation. No additional staff members were required for the implementation, as the program allows individuals to nap during scheduled break periods. Certain issues complicate the appropriate use of naps by medical professionals. Locating space for the nap has proven to be a major (and continuing) hurdle.

USE OF CAFFEINE. Physicians frequently use caffeine to stay awake and to increase alertness temporarily during on-call periods, but often its use could be more strategic. Strategic use of caffeine includes (1) knowledge of its onset (15 to 30 minutes) and duration of action (3 to 4 hours) and (2) use when alertness is required and the opportunity to sleep is minimal. Besides its alerting effects, caffeine produces an increase in awakenings and decreases the total nocturnal sleep time if ingested close to sleep opportunities. Long-term use of caffeine, common in our culture, produces tolerance to the alerting effect of the drug and hence should be avoided when using caffeine strategically. Nicotine is a stimulant that produces effects similar to those of caffeine.

While anesthesia professionals might get away with working when sleepy without affecting aggregate patient outcome that does not mean that issues of sleep deprivation and fatigue should be ignored. Falling asleep (a long microsleep or full sleep) while taking care of a patient is just not acceptable; it's surely not what any patient or their family has a right to expect. Thus, both the individual anesthesia professional AND the systems and institutions they work within need to address the fatigue issue systematically. It is clear that just placing limits on work hours, either for trainees alone (the current situation in many countries) or for fully certified personnel as well, cannot do so. Only an integrated approach aimed at improving individuals' sleep hygiene along with reorganizing the structure and processes of clinical work will stand any chance of ensuring that anesthesia professionals who are appropriately alert are always there vigilantly protecting their patient.

Aging Anesthesiologists

Human abilities cannot be maintained indefinitely as humans age. On average, performance on laboratory tests of discrete sensory-motor and cognitive skills can be shown to decrease with increasing age.[269] However, large differences are noted among individuals. Again, except at extreme points of performance failure (e.g., severe impairment of vision, hearing, or cognition), the contribution of isolated changes in physiologic or cognitive performance is difficult to relate to real work situations. The work environment is often rich with redundant cues involving multiple sensory modalities, and technologic compensation for physiologic deficits is common (e.g., hearing aids or glasses). Advancing age is associated with worsening performance when tasks involve single-solution or fluency-based definitions of effectiveness.[270] However, along with possible physiologic changes of age typically comes greater experience with a variety of situations. When efficacy is defined in terms of the diversity of strategies used, as well as by the social and emotional impact of solution choice on the individual, performance is remarkably stable and sometimes even improves in the latter half of life.[270]

For many individuals, the lessons learned from experience more than offset the modest degree of physiologic impairment that they face as they grow older. Issues attributed to "age" might instead be related to a longer period away from initial or recurrent systematic training. The originally well-trained practitioner who keeps abreast of the changing standard of care and who exercises emergency skills frequently is less likely to be affected by advancing age than is a marginal practitioner whose knowledge and skills were frozen immediately after completion of initial training. For anesthesia professionals who are enrolled in mandatory maintenance of certification programs this issue might be less serious.

Patient care is a socially-organizationally constructed activity. Aging anesthesiologists may be able to modify their practice type, reducing complexity of cases or eliminating on-call and post-call patient care. Other perioperative team members may also be available to support those who while still competent may be, on any given day, not at their best.

What do other industries do about this issue? In the United States, from 1959 to 2007 there was a limit at 60 years of age for airline pilots; this has since been changed to age 65. Many countries have a higher limit and some have no limit. Moreover, regulations require airline pilots to pass a class I medical examination every 6 to 12 months, aimed at identifying individuals with chronic medical conditions that place them at risk for sudden incapacitation. Simulations show that sudden pilot incapacitation during a high-workload phase of flight (e.g., approach and landing) leads to a significant rate of crashes, even when a second pilot is at the controls. These physical examinations may also weed out pilots with severe cognitive or sensory-motor deficiencies (vision in particular), but they are not designed to assess subtle aspects of changes in performance resulting from age. Airline pilots' flying performance is also formally assessed annually throughout their career both during real flights and in simulation.

For anesthesia professionals, by contrast, there are no statutory requirements for medical examination or formal performance checking, although individual institutions or practice groups may choose to impose testing requirements or to implement age-based reductions in daytime or on-call requirements. No doubt, the issue of age-related effects on anesthesia professional performance is likely to continue to be raised periodically for the foreseeable future.

Illness and Drug Use

Every anesthesia professional is vulnerable to transient illnesses, which in some cases probably reduce performance ability. All personnel are vulnerable to chronic medical conditions that could directly or indirectly affect their fitness and performance capability. The culture of the caring professions often leads individuals to continue to work with illnesses that would cause other professionals to stay at home or to seek medical advice. The performance-shaping effects of the illness can be exacerbated by the use of either over-the-counter or prescribed medications. The degree to which illnesses and medications affect professional performance in anesthesia is unknown.

PATIENT SAFETY ACTION BOX

Pilots use a mnemonic checklist to review the effects of potential performance-shaping factors and are instructed not to fly if they are impaired for any reason. One similar safety strategy in health care is the "I'M SAFE" approach,[271] promoted by the patient safety intervention strategy "TeamSTEPPS," which is explained more in detail later. "I'M SAFE" is a simple personal checklist to determine one's ability to perform safely concerning the factors: **I**llness, **M**edication, **S**tress, **A**lcohol/Drugs, **F**atigue, **E**ating and Elimination. The difficulty in anesthesiology is that the real-world organization and incentives of many practice settings do not provide mechanisms for personnel to excuse themselves if they are temporarily impaired and that there barely exist organizational structures and departmental understanding to promote such approaches (lack of "safety culture").

A more serious problem for anesthesia professionals is that of drug and substance abuse.[272-275] Nearly 15% of all doctors will become substance-dependent over their lifetime, and the incidence in anesthetists is almost 3 times greater than other physician groups. Including alcohol, studies describe up to 3.5% of anesthesiologists being addicted; if alcohol is excluded, drug addiction occurs in about 2.5%.[276,277] The degree to which small doses of alcohol or hangovers affect performance on complex, anesthesia

TABLE 6.3 Examples of Hazardous Attitudes and Antidote Thoughts[279]

Hazardous Attitude	Antidote Thoughts
Antiauthority: *"Don't tell me what to do. The policies are for someone else."*	*"Follow the rules. They are usually right."*
Impulsivity: *"Do something quickly—anything!"*	*"Not so fast. Think first."*
Invulnerability: *"It won't happen to me. It's just a routine case."*	*"It could happen to me. Serious problems can develop even in routine cases."*
Macho: *"I'll show you I can do it. I can intubate the trachea of anyone."*	*"Taking chances is foolish. Plan for failure."*
Resignation: *"What's the use? It's out of my hands. It's up to the surgeon."*	*"I'm not helpless. I can make a difference. There is always something else to try that might help."*

tasks is uncertain. The natural history of serious abuse of alcohol, cocaine, sedatives, or narcotics by anesthesia professionals is such that cognitive performance will at some point be seriously compromised, although addiction specialists frequently report that job performance is one of the last areas of life to become seriously impaired.[273,275,278] The period of time in which an addicted anesthesia professional's performance in the OR is significantly impaired may be a relatively small fraction of the total time during which drugs are abused. Although this in no way excuses the practice of conducting anesthesia while under the influence of drugs, it may account for the fact that reports of addicted anesthesiologists are, unfortunately, common, whereas reports of overt patient risk or harm resulting from an addicted physician's errors are unusual. A host of other threats to patient safety, including production pressure, fatigue, illness, burnout, and distraction will affect far more anesthesia professionals, occur more regularly, and pose greater safety risks to patients, but they do not carry the same level of risk to the professional's own life, nor the same social stigma, as does addiction. On the other hand, diversion of drugs from the patient who needs them to the addicted clinician for use or sale is a growing risk.

Professionals' Attitudes as a Crucial Part of Human Performance and Patient Safety

Attitudes are important components of one's abilities. They can affect performance as strongly as physiologic and cognitive performance-shaping factors. Psychologists studying judgment in aviators have identified five types of attitude as being particularly hazardous, and they have developed specific antidote thoughts for each of these, which are supposed to be verbalized by pilots whenever they find themselves thinking in that way.[279] The authors have adapted these to anesthesiology shown in Table 6.3.

The invulnerable and macho attitudes seem particularly hazardous for anesthesia professionals. They are compounded by production pressures to handle more cases in less time with fewer cancellations and less opportunity for preoperative evaluation. The feeling that a catastrophe "cannot happen to me" and that perfect performance can always be relied on to avert a disaster can lead to cavalier behavior and poor planning. It can alter thresholds for believing that abnormal data represent a problem, thereby leading to the fixation error of "everything's OK."

Expert human performance is the anesthesia professional's most powerful tool to safeguard the patient. However, planning to avoid catastrophe is likely to be more successful than battling to avert it. The economic and social realities of practice can cause these pressures to become internalized by anesthesia professionals, who then develop hazardous attitudes they might otherwise have resisted.

Under these conditions the usual protocols for elective case management must be adapted to seek the best outcome for the patient. In the final analysis, one must ensure that the patient's benefit is the primary criterion in such decisions, and one should establish a bottom line of safe planning, pre-use equipment checks, and patient preparation beyond which one will not be pushed. Even if surgeons, nurses, colleagues, or administrators pressure one to do things that one does not think are safe, no one will thank you if the patient suffers, nor will they come to your defense should litigation arise.

To simplify these decisions, many institutions have developed multidisciplinary written consensus guidelines on the preoperative preparation of patients that address the appropriate workup for patients with various medical conditions in different surgical urgency categories.

PATIENT SAFETY ACTION BOX

Sometimes it might seem appealing for a medical professional to emerge as a hero after a problem is solved or a complication is managed, but the challenge is to realize first that anesthesia professionals cannot rely primarily on heroism to achieve optimal safety, and second that in all likelihood no hero would have been needed at all if proper safety measures had been taken to begin with.

In their review *"Why hospitals don't learn from failures: organizational and psychological dynamics that inhibit system change,"* Tucker and Edmondson[280] describe a further aspect of professionals' attitudes that can have implications on safety*:* People are creative and they want to make things work for their patient. So, nearly every day they diligently work around problems and obstacles the best they can. However, the very acts of individual resourcefulness by such workarounds may mask the underlying systems issues that expose many patients to risk and thereby delay addressing successfully those very issues.

HUMAN FACTORS AT THE TEAM LEVEL

This section focuses on the human factors at the team level, exploring the key elements (a) effective communication including handoffs and the delegation of tasks; (b) the safety enhancing strategy "speaking up"; (c) aspects of status and hierarchy effects in teams; (d) teamwork including (e) leadership aspects.

Fig. 6.6 Stairway of Communication and Closed Loop Communication: The importance of proper communication. (1) Especially when dealing with complex situations under time pressure, but also during routine work, people tend to "mean" or "think" a lot, but "say" little. It is important to let other team members know what one thinks in order to create shared mental models of a situation. (2) For several reasons, not everything that is said is necessarily heard by those who should hear it. The sender needs to ensure that the message was heard by the receiver and the receiver needs to confirm the message (= closed loop communication). (3) Acoustic hearing and mental understanding are not the same. "Closely monitor this patient" might be clearly heard, but what is meant is open for interpretation on a large spectrum. Misunderstanding can result, but can be smoothed out. (4) Some tasks may be forgotten, making double checking necessary. Some tasks need time to be completed, some tasks may fail. No matter what, the team needs to know (= closed loop communication).

Effective Communication and Delegation of Tasks

The benefits of effective communication for patient care in anesthesia and the operating room have been repeatedly demonstrated.[281-284] However, the term effective communication is imprecise leaving much room for interpretation. In fact, communication is never a one-way street and effectiveness includes participation of all team members.[285] Based on research showing that teams unfortunately tend to communicate ineffectively, effective communication refers to both content and form.[286] Teams should routinely use and update information from multiple available resources, share key elements between team members, and strive to always communicate as clearly as possible.[286,287]

Closed Loop Communication. For example, addressing team members by name and engaging in closed loop communication (Fig. 6.6) can help avoid misunderstandings.[288-290] Closed loop communication includes (a) when the sender initiates communication, the receiver confirms that the communication has been heard by repeating the content of the communication and (b) when a delegated task is finished, the receiver gets back to the sender and the sender confirms the feedback. For instance, instead of saying *"Can someone call for help, please?"* closed loop communication presents as follows: *"Jeff, can you call for help, please."—"Yes, Megan, I will call for help immediately."—"Megan, I have called for help and they are on their way."*—"*Ok Jeff, thank you.*" El-Shafy and colleagues evaluated the effectiveness of closed loop communication in trauma settings of a level I trauma center in the United States, analyzing all verbal orders issued by the trauma team leader for order audibility, directed responsibility, check-back, and time-to-task-completion.[291] In total, 89 trauma videos were reviewed, with 387 verbal orders identified. Of those, 126 (32.6%) were directed, 372 (96.1%) audible, and 101 (26.1%) closed loop. On average each order required 3.85 minutes to be completed. There was a significant reduction in time-to-task-completion when closed loop communication was utilized. Orders with closed loop communication were completed 3.6 times sooner compared to orders with an open loop. The authors highlighted that closed loop communication not only prevents errors, but has the potential to increase the speed and efficiency with which tasks are completed in the setting of trauma.

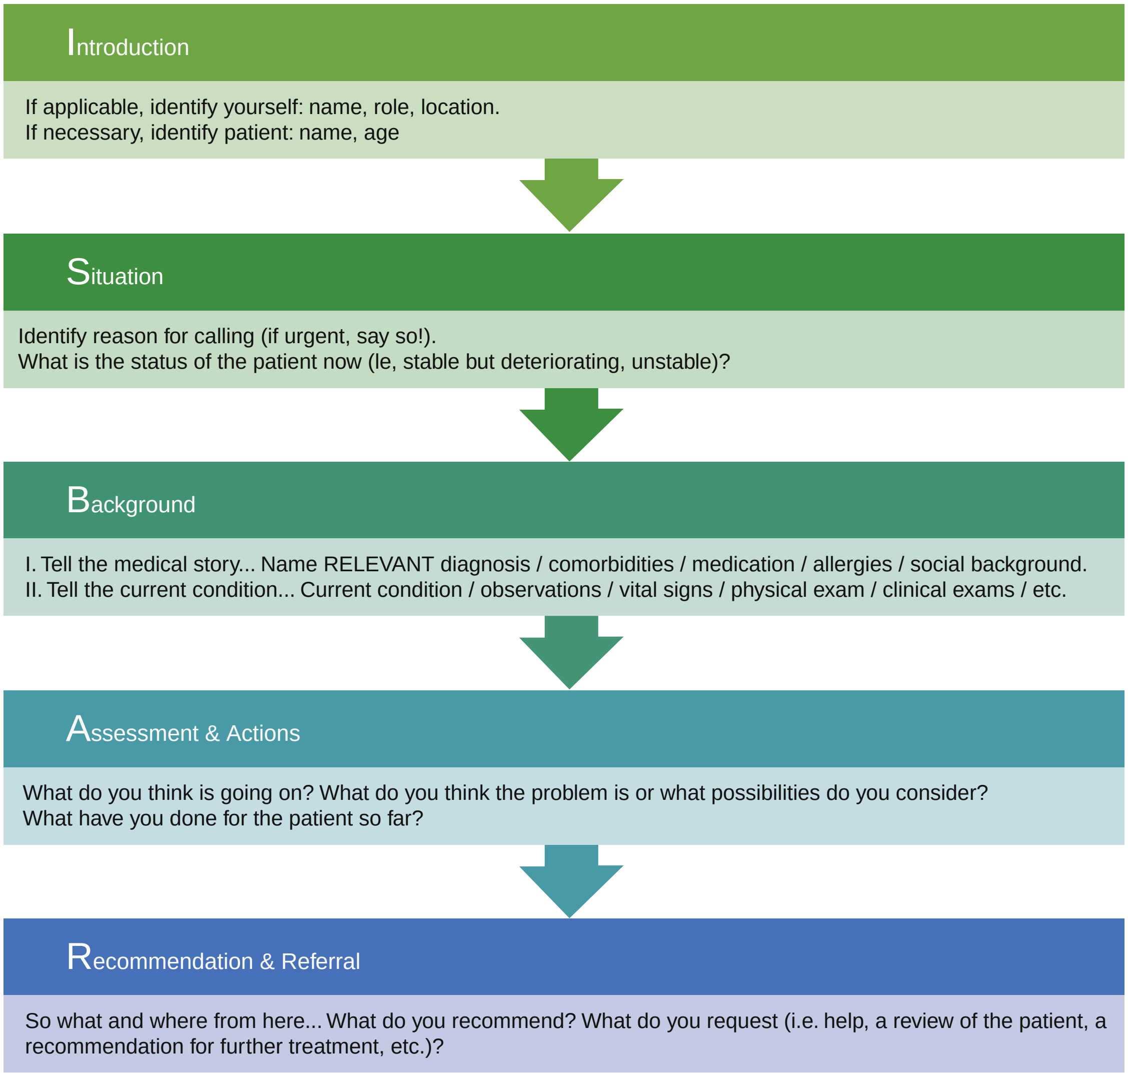
ISBAR Tool. Another effective communication tool especially useful for sharing information is the ISBAR concept (Fig. 6.7), often abridged to just SBAR. The acronym stands for **I**ntroduction, **S**ituation, **B**ackground, **A**ssessment, and **R**ecommendation. It originated in U.S. nuclear submarines and has also been used in the airline industry. ISBAR may be used variably by different members of the OR team.[292] Its use is associated with increased accuracy in communication and safety climate[293] and a decrease in communication errors[293] as well as in unexpected death.[294]

In the medical setting, ISBAR is a universally applicable communication tool that is usable in several settings, including for example face-to-face as well as telephone handovers in the OR or in the anesthesia post-anesthesia care unit. It also can be used for the briefing of new team members during emergencies and for briefing senior staff who has been asked for help. In the literature the slogan "Think—Talk—Write—ISBAR" can be found and characterizes the broad field of application of the idea. Shahid and Thomas give an up-to-date narrative review of the current literature on (I)SBAR, the challenges of communication among health care providers, and the proper use of the tool, and compares it to other communication tools that exist in order to assess their strengths and weaknesses.[295] For -detailed information the reader is referred to this review.

Because it assists the transfer of important information in limited time, ISBAR has been adopted by many health care organizations across the world. Medical associations and leading health care organizations, like the German Association of Anesthesiology and Intensive Care Medicine—Deutsche Gesellschaft für Anästhesiologie und Intensivmedizin (DGAI), the Australian Commission for Safety and Quality in Health Care (ACSQHC), the Institute of Healthcare Improvement (IHI), and the WHO have endorsed the (I)SBAR method as a standard communication tool, when appropriate, for health care providers. The experience in the United States is that SBAR has been adopted (in principle if not always in widespread practice) for nurses but is not frequently used by physicians.

PATIENT SAFETY ACTION BOX

Why use ISBAR (or SBAR)? It has the potential to improve patient care by enhancing transfer of information, responsibility, and accountability. It can improve patient safety by encouraging complete communication. ISBAR is an easy-to-remember memory prompt that helps providers (a) to prioritize what needs to be said by preparing consciously for communication, and (b) to set expectations on what will be



Introduction

If applicable, identify yourself: name, role, location.
If necessary, identify patient: name, age

Situation

Identify reason for calling (if urgent, say so!).
What is the status of the patient now (Ie, stable but deteriorating, unstable)?

Background

I. Tell the medical story... Name RELEVANT diagnosis / comorbidities / medication / allergies / social background.
II. Tell the current condition... Current condition / observations / vital signs / physical exam / clinical exams / etc.

Assessment & Actions

What do you think is going on? What do you think the problem is or what possibilities do you consider?
What have you done for the patient so far?

Recommendation & Referral

So what and where from here... What do you recommend? What do you request (i.e. help, a review of the patient, a recommendation for further treatment, etc.)?

Fig. 6.7 Example of the use of the communication tool ISBAR.

communicated (shared mental models). ISBAR can reduce barriers to effective communication across different levels of staff, professions, and disciplines. Its application should be expected for routine cases, which will then enable its use even during stressful events.

Handoff Protocols[*]. Another aspect of safe and effective communication concerns post-intervention handoffs and intraoperative transitions of care responsibility, which are known settings of risk for critical information to be lost.[296] Intraoperative anesthesia care transitions are known to be associated with adverse postoperative outcomes, with a similar effect size for attendings, residents, and nurse anesthetists.[297] Sometimes though the new person may be able to take a fresh look at the situation, catch errors, or find opportunities to improve care.

Handoff protocols are intended to minimize patient risk by creating a designated time and framework to ensure that crucial information is not missed during care transitions. There is an increased focus on formal protocols because the number of patient care handoffs has markedly increased in some settings due to work hours limits. Protocols can be divided into conceptual models (e.g., IQ—a reminder that the caregiver should inform the receiving provider about the details of the patient and case and then allow them to ask questions before leaving) or scripted models (e.g., I-PASS[298] which stands for **I**llness severity, **P**atient summary, **A**ction list, **S**ituation awareness and contingency plans, and **S**ynthesis by receiver, or I PASS the BATON[271] which stands for Introduction, Patient, Assessment, Situation, Safety Concerns [the] Background, Actions, Timing, Ownership, Next).

Another comparison can be made between verbal and written handoffs and also supplementing a primarily verbal handoff with written information. When a patient's care is being transferred to a different care team, such as when a patient moves between the intensive care unit and the operating room, a team-to-team handoff is beneficial because the report and questions about the patient are consolidated for both teams (e.g., time out for sign out).[299] A good handoff process should be used for every transition, including intraoperative transfers for breaks,[300] dropping off the patient in the PACU,[206] or changes from one anesthesiologist to another during a case. Using a checklist or structure can help prevent lapses, but regardless of the tool used, the goal is to provide clear and complete communication to protect the patient from medical errors.

---

Effective Delegation of Tasks. Delegation of tasks is sometimes ineffective leading to frustration on both sides: the person delegating and the person meant to perform the tasks. A common failing is when the delegation is incomplete and subject to assumptions, leaving too much room for interpretations.

The granularity of delegation instructions may depend on the personnel involved. For peer anesthesia professionals it may work to delegate a whole area of responsibility, such as "Sara, can you handle airway management please?," trusting that person to make the necessary decisions on their own. In other cases, especially with less experienced personnel, simply saying *"Michael, take care of the blood pressure"* may be insufficient because both the leader and the follower may have different assumptions of what that means in practical terms. With such a mismatch both parties may be unhappy. In such settings a more detailed delegation instruction may be needed, such as

"Michael, because our patient has a known hypertension and a risk for stroke, try to keep the diastolic blood pressure at or above 80 mm Hg. If necessary, give up to 500 ml crystalloid and, if necessary, small doses of ephedrine. If that doesn't handle it let me know. Any questions?"

PATIENT SAFETY ACTION BOX

Effective delegation of tasks involves sharing mental models of the situation and oftentimes also sharing concrete orders or suggestions about what one expects the other to do in order to fulfill the task to the other person's satisfaction. One reason why delegators do not use concrete delegation of tasks is because they think that it would take too much time or because they assume that the other person knows or should know what do to. Those few seconds to make it as concrete as the situation requires will probably pay off in the long run.

Asking Open-Ended Questions. A useful and simple means of communication, particularly in interprofessional and interdisciplinary settings, is to ask about other team members' points of view and plans using open-ended questions.[281,301]

Status and Hierarchy: Speaking Up

Speaking up refers to "*discretionary communication of ideas, suggestions, concerns, or opinions about work-related issues with the intent to improve organizational or unit functioning*" (p. 375).[302] Often the notion of speaking up implies doing so from below to above in the authority gradient. Without speaking up, problems cannot be identified, ideas will not be shared, and potential harm will not be prevented. This is particularly important in the multidisciplinary, complex, dynamic, and yet confined environment of operating rooms.[303] Here, a team member's speaking up to raise concerns about potentially risky or inappropriate actions of other team members may often be the final barrier to an emerging adverse event.[10,304-307] Unfortunately, speaking up is rare in teams in general and in operating room crews in particular.[308-310] In a survey of 137 chiefs of medical and surgical departments, 70% said that problems were not addressed and "elephants in the room" were common.[311] Simulation-based studies in anesthesia have demonstrated that in situations that need speaking up, only 40% to 70% of the participants did so.[312,313] For example, one such study showed that faculty anesthesiologists only spoke up: (a) 73% of the time to a surgeon who demonstrated profound sleepiness; (b) 14% of the time to a nurse who put a pathologist on speakerphone while the patient was awake and could hear; and (c) only 24% of the time to an anesthesiologist colleague who ordered the wrong treatment.[303] Creating conditions that encourage speaking up is particularly useful for crews whose composition is constantly changing, so members do not have time to develop as team.[314] This instability impedes the development of both norms to speak up as well as psychological safety, that is, the perception that there is no jeopardy to one's position if they do speak up.[315]

BOX 6.3 Raising Safety Concerns - the CUS Tool

The CUS tool[271] is used to clearly communicate and escalate a rising level of concern for any issue and to focus a team's attention on specific key phrases that are linked to raising concerns. When a team member uses the phrase *"I am **c**oncerned…"* it is to get the team's attention and to ensure that team members are listening. In order to escalate the concern, the team member would use the phrase *"I am **u**ncomfortable because…,"* finally escalating the concern with the phrase *"This is a **s**afety issue…."* Then the current action must be stopped ("Stop the line!") and evaluated before continuing. Having a common framework, consisting of those three escalating key phrases, provides teams with a standardized, easy-to-use, attention-providing communication tool to raise concerns. At the same time, team members have a clear idea of the level of importance associated with the concern, due to the escalating concept.

Strong hierarchies, which are prevalent in many hospitals, constitute a barrier to speaking up.[303,316-318] Even formal systems designed to promote it may actually inhibit staff from speaking up.[319] Leadership is a powerful tool in facilitating it: leaders can support speaking up by providing direction and coaching,[320] by using inclusive language,[321] by implementing debriefings to reflect on speaking up, and by establishing and maintaining a norm that considers such actions as socially desirable.[322] New research shows that people who do speak up are seen as more confident, competent, and of higher social status than those who do not speak up.[323]

Two explicit safety strategies that can be used for speaking up are, for example, the CUS tool (Box 6.3) and the two-challenge rule (Box 6.4).[271] But the basic requirement for both tools, for them to work properly and beneficially, like with any tool, is the organizational integration and acceptance of the tools (see section on organizational aspects of patient safety and safety culture).

BOX 6.4 Raising Safety Concerns - The Two Challenge Rule

The two-challenge rule[271] is another strategy that also empowers all team members to "Stop the line!" if they sense or discover an essential safety breach.

The two-challenge rule emphasizes the following:

- It is everyone's responsibility to assertively voice concern ***at least 2 times*** to ensure that it has been heard
- The team member being challenged must acknowledge ***with an active verbal response*** that concern has been heard
- If the safety issue still hasn't been addressed: Team members should take a stronger course of action or utilize supervisor or chain of command

PATIENT SAFETY ACTION BOX

Speaking up is never easy. It gets even harder if there is a difference in the hierarchy and experience level or if there is little positive organizational safety culture. Nevertheless, it is important to speak up if patient safety is in danger. The key to speaking up is often how to put things and when to intervene. Speaking up can be misinterpreted as a strategy to always tell colleagues what oneself would do differently. But speaking up should be used only in the case of a patient (or a colleague, or a piece of relevant equipment) at (potential) risk. To initiate speaking up it can help to have (organizationally) standardized phrasing, like for example, *"Excuse me, I see a patient safety issue here…."* Other systematic ways of expressing concern are the use of the CUS tool and the two-challenge rule. It also helps to explain one's thoughts and state a reason for the concern or the objection. For example instead of saying *"Succinylcholine…??? Do you really want to induce with succinylcholine???"* it is more helpful to say: *"Excuse me, in my eyes there is a patient safety issue using succinylcholine for induction. The patient has a potassium of 5.3 mmol/L so I think rocuronium would be better for induction, since the patient could get serious hyperkalemia and suffer cardiac arrest…"*

Teamwork

Teamwork can be defined as "*skills for working in a group context, in any role, to ensure effective joint task completion and team member satisfaction […. and includes] coordinating activities with team members; exchanging information; using authority and assertiveness; assessing capabilities; supporting others.*"[170]

Unlike teams in aviation, the military, and police and fire services, the OR team is unusual in that the command structure is ambiguous. Physicians (surgeon and anesthesiologist) are nominally superior to nursing and technical staff, but the two sets of physicians are coequally responsible for the patient during the immediate perioperative period.

Although surgeons were historically considered the "captain of the ship," with even a legal doctrine giving them responsibility for the actions of all other OR team members, this has long since formally fallen by the wayside. Nonetheless remnants of this old history remain in aspects of the organizational structure and culture of OR environments. Clearly though when both anesthesiologists and surgeons are jointly caring for a patient, they are both responsible, and this situation can lead to complex issues of command authority, hierarchy, and control. Cooper recently published a paper investigating the critical role of the surgeon-anesthesiologist relationship for patient safety.[324] Even though there is little research about this relationship, Cooper argues that the relationship for each surgeon-anesthesiologist dyad is perhaps the most critical element of overall team performance. His article explores functional and dysfunctional aspects of the relationship, identifies negative stereotypes each profession has of the other, and offers some suggestions on how to improve the working relationship.

Apart from the challenge of the coequal responsibility of the patient, the composition of teams in the OR holds some further challenges. Salas and colleagues defined a team as *"a distinguishable set of two or more people who interact, dynamically, interdependently, and adaptively toward a common and valued goal/ objective/ mission, who have each been assigned specific roles or functions to perform, and who have a limited life-span of membership"* (p. 4).[325] A team is distinct from a group in that a group is an ad hoc collection of individuals without a specific mission and without specific roles. In the OR, all team members have the common goal of a good outcome for the patient. However, considerable disagreement can exist on how to achieve this goal and which elements of patient care have the highest priority. These differences are probably traceable to the fact that the OR team is itself made up of several crews (e.g., surgery, anesthesiology, nursing, as well as sometimes technical personnel from several domains) each of which has its own command hierarchy, its own global properties (professional standing, culture, traditions, and history), and its own set of local goals and objectives for management of the patient. A critical component of the success of this process comprises the establishment and maintenance of a shared mental model of the situation. The greater the overlap in mental models the more likely that team members will predict, coordinate, and adapt.[13] To the degree that these objectives can be accomplished, the different individuals will be able to tailor their efforts toward a common goal.

The quality of teamwork influences clinical performance in anesthesia.[326] Strictly speaking, teams in the operating room and resuscitation teams are not teams in the traditional sense that exist for an extended period of time with a shared goal and fixed team membership. Instead, they are considered action teams: members may be assigned together ad hoc for a rather short tenure, and team membership may change repeatedly.[81]

This has implications for teamwork and training: such teams have limited time to develop and learn as a team.[314] Instead, they must team off the cuff—an ability that has been described as teaming.[285] Teaming includes four pillars: speaking up (see earlier section), collaboration (i.e., adopting a collaborative mindset and collaborative behaviors), experimentation (i.e., working iteratively and considering uncertainty as inherent in interactions), and regular and continuous reflection about teamwork. Briefings and debriefings have been shown to offer an infrastructure for reflection in anesthesia and the OR.[314,327,328] Particularly for action teams such as in the operating room, establishing and updating shared knowledge is challenging. According to Cooke and Salas, team knowledge is more than the sum of individual team members' knowledge.[329] They distinguished between team mental model and team situation model. To judge team knowledge, information is also needed on the broader aspect of team cognition, which involves team knowledge itself, team decision making, team situation awareness, and team perception. Establishing team cognition and adapting to changing requirements requires targeted communication among team members.[215,288,290,330-332] This may be done explicitly to avoid misunderstanding and check mutual assumptions, or implicitly, for example by talking to the room.[153,290,301,333]

Leadership

Whereas in aviation the roles of the captain and the first officer are carefully defined and involve separate but interrelated tasks, in anesthesiology the patient care roles and responsibilities of different members of the crew of anesthesia professionals—whether experienced or in training—are rarely predefined or made explicit. For example, a trainee is often expected to do all tasks with only occasional assistance from the supervisor. Leadership is pivotal in critical, non-routine, and highly complex situations in anesthesiology.[82,334,335] It includes a variety of functions such as composing team, defining mission, establishing expectations and goals, structuring and planning, training and developing, sense making, providing feedback, monitoring the team and managing its boundaries, performing team tasks, challenging the team, solving problems, providing resources, encouraging team self-management, and supporting social climate.[336] Some of these leadership functions may be shared among crew members.[335] A senior leader of a trauma team may dynamically delegate or withdraw certain active leadership roles to junior leaders.[337] While sharing leadership can be effective, it may require the team to know and discuss how to work well in this fashion[338] (see also later section on CRM, section "CRM Key Point 4"). This is important especially in highly dynamic, time-critical situations such as resuscitations in which leadership is critical for performance and has to be adapted to changing task and coordination requirements.[339,340] Behavior observation studies on leadership in acute care have shown that leadership behavior is positively associated with performance during critical and barely standardized situations, but negatively associated with performance during routine and highly standardized situations.[85] In addition, leaders should be role models of civil and respectful interaction as this is important for high and safe performance.[341,342]

PATIENT SAFETY ACTION BOX

There are many kinds of situations where it is not clear who is the team leader in a medical setting. For example, to nurses or even to the physicians involved, it might be unclear who is the team leader when two doctors of the same profession present during an emergency. Leadership may change as personnel of different seniority or expertise enter or exit the scene. It is helpful to clarify roles as necessary. For example: *"Thank you for the handover. Now I will take over"* or *"Thank you. You stay in charge and I will assist you,"* or if in doubt ask *"Just to double check: Am I still in charge or do you want me to assist you?"* or from the perception of a nurse *"I am sorry, but to better coordinate my work: who is in charge now?"*

A particular issue of hierarchy is known as cue giving and cue taking, in which people give off cues (often without even knowing it) that are taken up by others.[343] People lower in a hierarchy are very sensitive to cues emitted by their superiors, which can inhibit action or even questions from subordinates. Such cues may be read as *"don't bother me," "don't question me," "I know what I'm doing; you don't,"* or *"I just checked on that and it's fine,"* thus inhibiting speaking up. A qualitative, descriptive study on nontechnical skills in Sweden revealed that anesthesia nurses view anesthetists as excellent if they are calm and clear in critical situations, and able to change to a strong leading style.[344] More on leadership in anesthesia can be found later in the associated section of "CRM principle 4."

PATIENT SAFETY STRATEGIES AT THE INDIVIDUAL AND TEAM LEVEL: CRISIS RESOURCE MANAGEMENT AND OTHER TRAINING CURRICULA

This next section is about how to minimize the negative human factors aspects of the anesthesia professional's physical, psychological, and organizational work environments and how to strengthen the positive aspects of individual and team performance. The CRM approach mentioned earlier is a useful organizing principle for tackling these issues. Below the authors (1) give a general explanation of the strategy and its history, (2) introduce the 15 key principles of CRM, (3) discuss the application of CRM in crisis as well as in routine medical situations, (4) cite evidence that CRM is beneficial in health care, and (5) briefly touch on other well-known team training curricula such as TeamSTEPPS and Medical Team Training (MTT).

Crisis/Crew Resource Management

Crisis resource management (CRM) in medicine, sometimes also referred to as crew resource management, is an effective safety strategy concept and tool adapted from the domain of aviation and modified to the needs of health care. Gaba traditionally defines CRM: *"CRM is the ability to translate the knowledge of what needs to be done into effective team activity in the complex and ill-structured real world of medical treatment."*

In overview, CRM means to coordinate, use, and apply all available resources to optimally protect the patient—at an individual as well as at a team level. Resources include all the personnel involved, along with all their skills, abilities, and attitudes—albeit also with their human limitations. Machines, devices, and information sources, including cognitive aids, are also critical resources. In addition, CRM provides effective strategies that cover typical safety pitfalls attributed to the five main elements of human-factor-related behavior as introduced earlier. The underlying scientific basis of CRM is formatted into 15 practical CRM key principles health care professionals can apply during work (Box 6.5).

CRM was introduced in aviation by airlines working with NASA originally as cockpit resource management in the mid-1980s after some sentinel airplane crashes. It later was renamed crew resource management to acknowledge the importance of the crew, not only those in the cockpit. CRM from that time on was and still is considered to be a successful safety strategy in aviation and is also part of safety strategies in other industrial and military settings. Interestingly, even though these industries maintain CRM principles and CRM training as crucial parts of their safety processes, they do so without what evidence-based medicine would call "level 1 evidence"—sound randomized trials—to justify this.[11,345] In fact, such evidence would be impossible to collect.

A similar program for anesthesiology was first developed by Gaba, Howard, and associates at the Veterans Affairs (VA) Palo Alto Health Care System and Stanford School of

BOX 6.5 Crisis Resource Management—Key Points in Health Care

- Know the environment.
- Anticipate and plan.
- Call for help early.
- Establish leadership and followership with appropriate assertiveness.
- Distribute the workload. Use 10 s for 10 min concept.
- Mobilize all available resources.
- Communicate effectively—speak up.
- Use all available information.
- Prevent and manage fixation errors.
- Cross and double check. Never assume anything.
- Use cognitive aids.
- Reevaluate repeatedly. Apply 10 s for 10 min concept.
- Use good teamwork. Coordinate with and support others.
- Allocate attention wisely.
- Set priorities dynamically.

The key points are derived from the publication of Rall and Gaba in the 6th edition of Miller's Anesthesia[559] and presented here in their updated, current version.

Medicine [109,127] originally as anesthesia crisis resource management (ACRM). It was modified from the aviation-based CRM principles to better suit the medical needs. The ACRM-like curricula have since been adopted by training centers worldwide for a variety of health care domains.[346] A detailed description of the ACRM course is provided.[347] More in-depth information on CRM in anesthesiology is provided in related safety literature[11,59,123,127,348] and in both the first (1994) and second edition[14] of the pioneering *Crisis Management in Anesthesiology* textbook by Gaba, Fish, Howard, and now Burden. Note that the term crisis does not mean that these principles only apply in such dire settings; instead, they apply to everything in patient care but are most pronounced in challenging situations. In addition, the pioneers of ACRM wished to retain the CRM acronym without using terms like cockpit or crew that were not familiar in health care.

The 15 Key Principles of Crisis Resource Management

The key points of CRM as they apply to anesthesia care have been steadily updated and expanded over time and are based on the research presented in the earlier sections. The 15 CRM key principles by Rall and Gaba (see Box 6.5) cover the content of the five main elements of human-factor-related behavior as introduced earlier: communication, teamwork, task management, decision making, and situation awareness (see Fig. 6.5). The CRM principles translate the theoretical content of those areas that are known to be important into handy and very applicable action strategies for health care professionals.

Looking closely, one can recognize that the different principles overlap in their content and aim in many cases. This way, different members and professions of a team can apply different CRM principles at different points of time during patient care, minimizing the risk of an error or harm to occur. Clinicians are not expected to memorize these principles; rather, the authors expect that they will be embedded into regular training and practice (see later section "How Can Crisis Resource Management Related Skills be Learned, Trained and Maintained").

Some of the principles may seem obvious or self-evident. However, from our experience in clinical work and simulation team training it is in fact *not* trivial to apply these principles in the real world. In the following sections the 15 CRM key points are introduced in detail.

Know the Environment (CRM Key Point 1). Knowing fully the environment of work is critical. Environment refers to equipment, supplies, processes, and people, as well as how they vary from case to case, or from location to location, time of day or day of the week. This knowledge reduces stress in the case of an emergency and provides more available mental capacity and prudence to deal with the case. It is important to know who can be asked for help, how to mobilize help quickly, and how long it will take help to arrive. Like pilots, anesthesia personnel can be expected to know in detail how to use all equipment and supplies, which in anesthesiology includes anesthesia machine, defibrillator, infusion and blood administration system as well as how to troubleshoot them or switch to backup devices. The experience of the authors as clinicians and teachers in real and simulated anesthetic cases suggests that many anesthesia professionals lack sufficient depth of knowledge or skill in the operation of their equipment. That these systems are not always designed optimally from a human factors standpoint only increases the need for the individual clinician to thoroughly learn about and practice with all their features and pitfalls.

PATIENT SAFETY ACTION BOX

Know Your Environment

- Know how to call for help and how to call a code in the event of a cardiac arrest or other major emergency.
- Know who to call for different kinds of problems or emergencies; learn the emergency numbers (or they may be present on available cognitive aids)—always ask for it if uncertain.
- Use any spare time at work to delve into the details and practice with devices or features that are rarely used. Some equipment (e.g., fiberoptic scopes) can be appropriately used during routine cases to stay in practice with its use.
- Be involved with organizational processes of identifying and implementing needed changes in different aspects of the environment to improve quality and safety.

Anticipate and Plan (CRM Key Point 2). Anticipation is key for goal-oriented behavior and it also helps avoid unpleasant surprises. Anesthesia professionals routinely consider in advance the requirements of a case and plan for its key milestones. In addition, they must imagine what could go wrong and plan ahead for possible difficulties. Savvy anesthesia professionals expect and are prepared for the unexpected. And when it does strike, they then anticipate what could happen next and prepare for the worst. In this context people often talk about "staying ahead of the game" or "not falling behind." Resources can be mobilized and used on the fly, but it is better if their possible need is anticipated and planned for.

For any case, a sound plan matches the anesthetic technique to the patient's disease state, the technical requirements of surgery (e.g., position of the patient), the anesthesia equipment available, and the skills of the anesthesia professional. It also includes specific backup procedures and contingency plans to be used if the original plan fails or needs to be changed. Often, faulty plans can result when underlying disease states are missed or ignored because of inadequate data gathering during preoperative evaluation. Poor planning may also result from the hazardous attitude of invulnerability. Note that a faulty anesthetic plan will expose the patient to risk even if it is carried out perfectly.

For anticipating and planning to be most effective, it should ensure the coordination of all members of the patient care team. One way to do so during routine cases is the use of briefings.[217,328] Over the last 10 years there has been a major movement to formalize such briefings (e.g., mandatory preoperative briefing of the WHO Surgical Safety Checklist, Patient Safety Huddles).

PATIENT SAFETY ACTION BOX

Anticipate and Plan Ahead

- In order to be prepared it is important to know what to potentially expect.
- For proper preparation it helps to imagine possible difficulties or complications before each case and mentally prepare for alternatives or actions. If in doubt it is better to err on the side of extra preparation.
- Perform anticipation and planning with your team: encourage colleagues to speak up; for challenging cases review in depth the primary plan (plan A) as well as the alternate plans B, C, D, etc.

Call for Help Early Early Enough to Make a Difference (CRM Key Point 3). Calling for help is associated with better individual and team performance.[75] Knowing one's own limitations and calling for help early are signs of rationality, strength, and patient-centeredness. Trying to handle everything alone or toughing out a critical situation is dangerous and unfair for everyone. The decision of when to call for help is complicated, but the key point is to do so early enough that the assistance can make a difference. A call so late that the patient is beyond rescue is futile. Knowing in advance who might be available and planning how you would use them will facilitate their utility.

Some typical triggers for calling for help that apply to any anesthesia professional at any level are (1) when there are too many tasks to do, (2) when the situation is already catastrophic (e.g., cardiac arrest, difficulty securing the airway), (3) when serious problems are becoming worse or are not responding to the usual maneuvers (or both), and (4) when you do not know what is going on.

For novice anesthesia professionals, calling for help very early is frequent as they are not expected to handle any critical aspect of a case (e.g., induction of anesthesia) without supervision or assistance. For experienced personnel it will be less frequent, as they are fully able to handle more things alone, but mobilizing help is still critically important. Many situations that would spin out of control can be readily resolved with appropriate and timely assistance.

Whereas prior research on these kinds of backing-up behavior has indicated that it is beneficial to teams, nothing is perfect. Barnes and colleagues published a critique of aspects of backing-up behavior in their article "Harmful help,"[349] citing for example decreased work on subsequent tasks after receiving high amounts of backup. A related concept is that of social shirking in which a task that is typically done separately by two people, to gain redundancy, instead is shirked (dropped) by one or both of them assuming that the other is taking care of it.[350]

PATIENT SAFETY ACTION BOX

Call for Help Early Enough to Make a Difference There are different conceptual categories of help. One can refer to them as hands help (to do things) versus head help (to assist in thinking). Providing bits of key information even during the call for help may assist incoming personnel to be thinking or planning for the possible needs. Calling for help will only succeed in sites with an organizational culture that approves and supports it (see later section on "safety culture"). If someone who calls for help appropriately but early gets criticized or even bullied by colleagues or senior leaders such pro-safety behaviors will likely be extinguished.

Establish Leadership and Followership With Appropriate Assertiveness (CRM Key Point 4). Leadership involves structuring the team, planning, deciding, and distributing tasks. Leadership does not imply knowing more than everyone else, doing everything alone, or putting other people down. Followership is as important as leadership. Team leaders and team followers are jointly responsible for the well-being of the patient (see earlier section on "speaking up"). Since speaking up requires the crossing of many personal and interpersonal hurdles (e.g., fear of repercussions or arising disadvantages),[307] team members may need explicit invitations to contribute and shows of appreciation by the team leader, sometimes referred to as leader inclusiveness.[351,352]

Wacker and Kolbe[82] wrote about leadership, followership, and teamwork in anesthesia:

> *"Intuitively and empirically, leadership and teamwork are essential for team performance, patient safety, and patient outcomes in anesthesia and perioperative care. [...] Current research supports the concept that little explicit leadership is usually required during standardized routine work, but active and even directive leadership is important in unexpected, novel, or stressful situations."* (p. 200)

In their work they give an overview of how leadership practices in anesthesiology optimally change (implicit vs. explicit team coordination) according to clinical work phases and special situations (routine situations with low or high task load; unexpected minor or major events; initiation and maintenance phase). Rosenman and colleagues give a systematic review of leadership and leadership training for health care action teams.[353,354]

PATIENT SAFETY ACTION BOX

Establish Leadership and Followership With Appropriate Assertiveness Whenever people work together, conflict can ensue. Anyone on the team may need to diffuse conflicts to focus the team on care of the patient. One approach is to explicitly ask the team to concentrate on *what* is right (for the patient), not on *who* is right. Conflicts should be settled after the clinical event is resolved. As the leader, strive to have an open ear for the concerns of team members and actively invite them to express their opinion (for example, *"Do you have any other suggestions...?"* or *"The patient is deteriorating—I think we need to intubate him; what do* *you all think?"*). Team members need the confirmation that concerns and encouragement are appreciated. Alternate views may or may not change the leader's approach, but if they are not voiced there is little chance for a modification.

Distribute the Workload. Use the 10-Seconds-for-10-Minutes Principle (CRM Key Point 5). One major aspect of strategic control of attention is the active management of workload. Rather than passively dealing with rising or falling workload, the anesthesia professional actively manages it. Among others, Schneider and Detweiler[240] and Stone et al.[130] described the theoretical basis for a variety of strategies of workload management. These strategies were addressed specifically for anesthesiology by several investigators.[108,111] The anesthesia professional actively manages workload by the following five techniques:

1. *Avoiding excessive workload situations* (i.e., by anticipating and planning, CRM key point 2; calling for help early, CRM key point 3). Experts may choose techniques and plans that reduce the workload (especially when their individual and team resources are limited), even when those plans are otherwise slightly less desirable from a technical standpoint. For example, a single anesthesia professional working alone may opt not to use a high-tech, high-workload monitor (e.g., TEE) for a given case because the effort to use it might outweigh the likely information gained.
2. *Distributing workload over time* (i.e., by setting priorities dynamically, CRM key point 15). The anesthesia professional can prepare for future tasks when the current load is low (preloading) and can delay or shed low-priority tasks when the workload is high (offloading). Resources that require a significant amount of workload to prepare, such as vasopressor infusions, are often made ready before the case starts. Many tasks are made up of several subtasks, each of which has a finite duration. Because close attention may not be required during each of these subtasks, they can sometimes be interleaved with a fixed amount of attention (multitasking/multiplexing, see earlier section).
3. *Distributing workload over personnel* (i.e., by applying the actual CRM key point 5; by coordinating the team, CRM key point 13). When workload cannot be distributed over time and when additional people are available, tasks can be distributed to them with certain considerations: (a) Some resources can be handled by the individual anesthesia professional, whereas others require additional personnel; (b) Some tasks are completely incompatible, for example any activity that requires being gowned and gloved will preclude that individual from performing nearly all other tasks; (c) In very time-sensitive situations distribution over personnel may be needed whereas for more routine situations a single individual may be sufficient for the same set of tasks.
4. *Changing the nature of the task.* The nature of a task is often not fixed. They can be executed to different standards of performance; as standards are loosened, the workload required to perform them is reduced. For example, during periods of massive blood loss, the anesthesia professional focuses primarily on administering blood and fluids and on monitoring blood pressure. The acceptable limits of blood pressure may be widened to reduce the need for more frequent interventions.
5. *Modifying distractions and offloading routine activities.* In addition to the attentional demands of the anesthesia professional's core tasks, any clinical environment may be full of distractions. Expert anesthesia professionals modulate the distractions by eliminating them when the workload is high and allowing them to occur when the workload is low (to improve morale and team building). Similarly certain routine tasks (e.g., entering non-critical information into the anesthesia record) or courtesy activities (e.g., tying the gown of a surgeon or nurse) may be performed by the anesthesia professional only when workload is low, but not when it rises.

PATIENT SAFETY ACTION BOX

Distribute the Workload A team leader should try to stay free of tasks in order to observe, gather information, coordinate, distribute, and delegate tasks. This is because mental capacity of human beings is limited—multitasking leads to often unrecognized errors. Within the operating room this may not be possible until several skilled personnel arrive to help. Even then, there can be some tasks which the leader decides to perform while still being at the center of the team; for example they might choose to be the person administering IV drugs linking decision to action without a communication step. There is no single arrangement of personnel or tasks that is perfect for every situation.

Appropriate assertiveness is important. A frequent observation in simulations and real cases is that anesthesia professionals may be too quiet or too casual, even for situations that demand urgency and assertiveness. But choosing the appropriate level and style of assertiveness is also important because being excessively assertive, especially for non-critical situations, will anger or annoy co-workers and lead to suboptimal results.

Exercising effective followership (see CRM key point 4, exercise leadership and followership with appropriate assertiveness), team members should also look actively for work that needs to be done. The team leader should not have to think of and order every single task or activity. Proper communication will be needed to coordinate the work (see CRM key principle 7, Communicate effectively).

PATIENT SAFETY ACTION BOX

Leaders should try to sensibly prioritize tasks to single individuals or to delegate one task at a time to each person, for example, *"Mary, go and call for help. Peter, go and get the emergency cart. Michael, draw up epinephrine 100 µg per mL."* Team members should speak up if they get too much work allocated at once or when the priorities aren't clear (e.g., *"I can only do one of those things at a time, which should I do first?"*).

We always have 10 seconds! Patient care is very rarely a high-speed discipline where seconds matter—initiating CPR is one example. Usually patients deteriorate in minutes to hours. Despite the stress and intrinsic pressure to perform immediate actions ("do something, do something now!") there is often some time to think of a plan. Trying to be too fast may lead to avoidable errors.

To address this Rall and colleagues developed the 10-seconds-for-10-minutes principle, meaning, metaphorically,

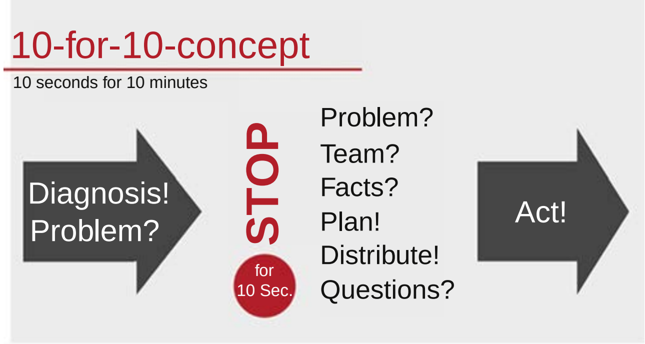

Fig. 6.8 The “10-seconds-for-10-minutes-principle”—“10-for-10.”[563] When *making a diagnosis* or *feeling stuck,* perform the 10-seconds-for-10-minutes team timeout and check to see “what the biggest problem is right now” *(Problem)*. Clarify this with all available team members *(Opinions)*. Gather the information available *(Facts)*. Plan the treatment, including the desired sequence of actions. Distribute the workload by assigning tasks and responsibilities. *Check actively* with all team members about any further concerns of suggestions. Then act as an organized team. (Figure provided by M. Rall.)

spending 10 seconds in order to achieve a better coordinated team for the next 10 minutes. Stopping for symbolically 10 seconds in an emergency feels counterintuitive, but once used to it, it is a very effective way to improve performance and patient safety. The 10-for-10 principle has spread to many health care settings (anesthesia, ICU, prehospital, etc.).

The concept can be extended to mean that sometimes an investment of time in an activity—even many minutes—can yield big dividends in various ways (including time saved) in the future. The benefit of strategic investment of time appears to be greatest in key situations, such as (a) the making of a provisional diagnosis and the beginning of treatment, (b) planning for complex interventions, or (c) when the team feels stuck because the initial diagnosis seems incorrect, or when the usual treatment of a known problem is not working (Fig. 6.8).

Research findings show that information sharing (see also CRM key principle 8, Use all available information) can be enhanced by structuring team discussions.[355] The 10-for-10 principle offers one way to encourage and facilitate such deliberations.

PATIENT SAFETY ACTION BOX

When applying the 10-for-10 principle, it helps to use a key word or a key sentence for the team to pause for a moment in order to initiate the 10-for-10 break (e.g., *“Stop, everybody pause for a moment and let’s summarize where we stand…”* For the 10-for-10 to work it is important for everyone to stop any non-critical action and for the leader to explicitly invite the whole team to participate (e.g., *“I want you all to stop whatever you are doing and I want to shortly summarize together where we stand. This seems to me like an anaphylactic reaction. What do you all think? Any other diagnoses in the differential?”* The 10-for-10 principle in general can be initiated by any team member, but it remains the decision of the team leader whether or when to execute it.

Mobilize All Available Resources (CRM Key Point 6). In case of an (imminent) emergency, everyone and everything necessary to help the patient should be mobilized, including personnel (CRM key principle 3, Call for help early), equipment, and organizational structures (radiology, other medical specialties, etc.). It is important to know which resources are available and with what delay (CRM key principles 1, Know the environment and 2, Anticipate and plan). On the human side, the anesthesia professional’s knowledge and skills, constrained by human factors and one’s own human deficiencies, is the most important resource, complemented by the helpers who can be brought to bear.

PATIENT SAFETY ACTION BOX

Mobilize All Available Resources When applicable think of all the team members, not just the anesthesia professionals or technicians. In a tough situation everyone should be willing to help but they do not always know how. The other professionals have many skills, some unique. Even relatively untrained personnel (housekeeping staff or orderlies, for example) may be able to help in some tasks.

Communicate Effectively—Speak Up (CRM Key Point 7). Good teamwork depends on everybody’s being on the same page and on coordinating efforts. Communication is a very important vehicle to achieve good teamwork. It is like the glue that holds the disparate members together. Even though anesthesia professionals speak to each other all day long, effective communication is actually challenging, especially in a stressful situation. Based on research showing that teams unfortunately tend to communicate ineffectively,[356-358] effective communication refers to both content and form.[286] Many aspects make communication difficult: for example unspecified assumptions, lack of a shared mental model, hierarchy, acoustics, high mental workload, and time pressure (see earlier sections).

When dealing with complex situations under time pressure, people tend to “mean” a lot, but “say” little. Fig. 6.6 shows the closed loop communication, a systematic model of proper communication, ensuring that other team members know what one means, says, understands, and does in order to create shared mental models.

PATIENT SAFETY ACTION BOX

Communicate Effectively—Speak Up In order to communicate assertively and effectively, these approaches help:

- Do not ordinarily raise your voice, but do so if necessary to get others’ attention.
- State your commands or requests as clearly and as precisely as possible. This is very difficult in a crisis, and it takes practice.
- Address people by their names if possible or search for eye contact before speaking. Despite the fact that anesthesia professionals hate to be called “anesthesia” (i.e., address people by function) routinely, there is not much choice but to do likewise to others in a crisis when you do not know their names. Avoid unclear assignments into thin air like *“Can someone monitor the saturation…,” “Someone has to call for help…,” “I need more propofol…,” “We need more fluids…”*
- Use closed loop communication (see also earlier section):
  - Read back —If you received an assignment, repeat what you heard (i.e., Task: “Peter, I need epinephrine 10 µg per mL.” Answer: “Ok Mary, I’ll draw up epinephrine 10 µg per mL.”

  - Feedback—Give feedback when you are done with an assignment and also give feedback on what you did, even if it did not work or if it is not satisfying (i.e., "Mary, I got the defibrillator. It's right behind you. Do you want me to set it up?").
  - Get back—If someone does not reply or react to you, they might not have heard it or were busy. Ask further questions, wait for acknowledgment, and wait to speak until they are ready to listen.
  - Ask back—If you did not hear what the other person was saying or if you did not understand the assigned task, you should clarify matters.
- Accustom yourself to using the correct dosage indication when delegating the drawing up or the administration of medication (i.e., say *"Give 20 mg of propofol"* instead of *"Give 20 of propofol"* or say *"Draw up epinephrine 100 μg per mL"* instead of *"Draw up epinephrine."*
- Ask questions, especially if you do not know how to proceed. *"Ok, team. Right now I don't have any further ideas how to proceed. What should we do next?."*
- If you explain your thoughts or objections, this will help the team to understand better. For example, do not just say *"Get the defibrillator"* (thinking to yourself *"get the defibrillator so that we're prepared if we need it")*. Say instead what you mean: *"Get the defibrillator. We don't need it yet, but I want to be prepared in case we do…."*

Use All Available Information (CRM Key Point 8). Anesthesiology is particularly complex because information must be integrated from many different sources. In emergencies anesthesiologists often have only limited and indirect information on the patient, including those immediately at hand (the patient, non-invasive monitors, the anesthesia record), secondary sources such as the patient's chart, and external sources such as cognitive aids (see CRM key principle 11) or the Internet. Information provided to nurses and physicians who join an ongoing emergency can be unreliable.[355,356] The simulation study of Bogenstätter and co-workers showed that 18% of the information given to newcomers was inaccurate.[356]

Because of the various sources of unreliability of information (artifacts, transients, and miscommunications) various steps of verification and data fusion are needed to provide the best basis for problem recognition, identification, diagnosis, and management (as indicated in the cognitive process model of the anesthesiologist—see earlier section).

PATIENT SAFETY ACTION BOX

Use All Available Information Be aware of the flow of time when considering information streams. Anesthesia can be very dynamic. Vital signs that were satisfactory three minutes ago can change quickly. For periodic non-invasive monitoring—say an automatic blood pressure cuff—we are constantly trading off the rate of recurrence of the measurement against the potential complications of too frequent use. The typical 5-minute interval will leave room for hidden changes should the patient become unstable, a problem exacerbated by the higher likelihood that the next measurement will be more difficult for the device to make adding more time to obtain a reading. This of course is why we sometimes opt to invest time, effort, and a small risk to place an arterial catheter for continuous measurement.

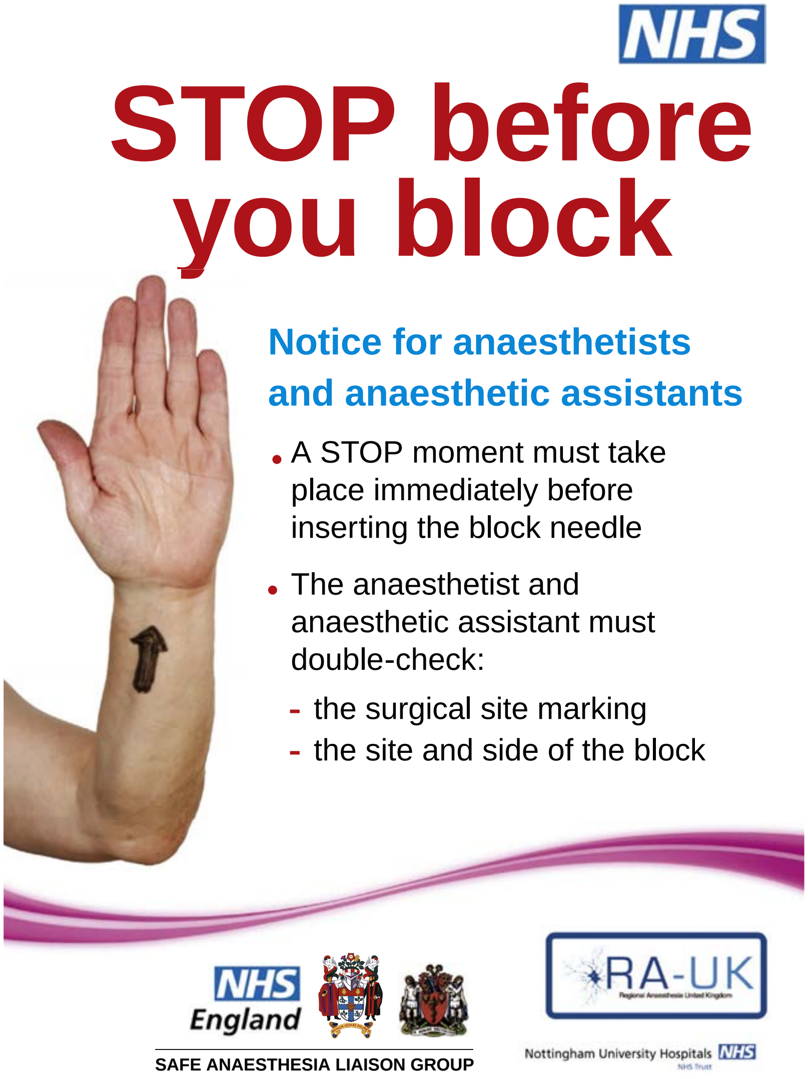
Prevent and Manage Fixation Errors (CRM Key Point 9). Human decisions and actions are based on an instantaneous mental model of the current situation (see earlier section on "core cognitive process model of anesthesia professional"). If the model is erroneous, the decisions and hence the actions will probably be wrong. Faulty reevaluation, inadequate plan adaptation, and loss of situation awareness each can result in the type of human error termed fixation error.[138] A fixation error describes a mental model of a situation that is persistently faulty despite sufficient evidence to correct it. A fixation error therefore leads to a persistent failure to revise a diagnosis or plan, even though readily available evidence suggests that a revision is necessary.

Three main types of fixation errors are recognized[137-139] and described in Box 6.6. Each represents an extreme relative to another; it is usually advantageous to aim for the sweet spot between the extremes. For example, regarding "This and Only This" versus "Everything But This," usually people want to hone in on the one most likely cause of a problem in order to properly address it, while still keeping an open mind for other possibilities. Occasionally the extreme is required—if there is no pulse, initially CPR must happen with no delay (this and only this) regardless of the underlying cause. Conversely, sometimes one must delay treating a possible cause so as to find out what is really going on. And if we never act as if everything is OK every routine case would turn into chaos. One's behavior must be fluid so as to navigate optimally toward or away from the middle ground as needed.

BOX 6.6 Fixation Errors

Three main types of fixation errors[137-139] are recognized and should be understood:

- Fixation Error # 1: *"This and only this" or "cognitive tunnel vision."* In this type of error, attention is focused on only one possibility. Other alternatives (possibly or actually correct) are not taken into account (i.e., There is profound hypotension and tachycardia; the patient must be hypovolemic, there must be bleeding [disregarding anaphylaxis, cardiogenic shock, excessive vasodilator administration, etc.]). The available evidence is interpreted to fit the initial diagnosis or attention is allocated to a minor aspect of a major problem.
- Fixation Error # 2: *"Everything but this."* In this type of error, attention is persistently focused on the search for further (irrelevant) information or diagnosis resulting in the failure to treat a probable cause and commit to the definitive treatment of a major problem. (i.e., Hmm… there is tachycardia, maybe it's light anesthesia, maybe it's hypovolemia, maybe it's… and there's hypercapnia maybe it's the CO_2 absorber, maybe it's… and there's fever, maybe the patient is septic, and… without ever committing to either definitively rule out, or else treat for—"actually all these signs point to malignant hyperthermia so I'm going to treat it as such").
- Fixation Error # 3: *"Everything is OK."* This is the persistent belief that no problem is occurring in spite of plentiful evidence that it is. In this type of error, all abnormalities may be attributed to artifact or transients. Possible (pre-) signs of a catastrophic situation are dismissed. (i.e., "The blood pressure cannot be so low. Probably the blood pressure cuff does not measure right. That is alright."). Another form of this type of fixation error is the failure to actively transition from routine mode into emergency mode when the situation demands it. A failure to declare an emergency or to accept help when facing a major crisis may stem from denial that a serious situation is actually occurring.



NHS

STOP before you block

Notice for anaesthetists and anaesthetic assistants

- A STOP moment must take place immediately before inserting the block needle
- The anaesthetist and anaesthetic assistant must double-check:
  - the surgical site marking
  - the site and side of the block

NHS England

When working alone, an anesthesia professional can deliberately change perspectives (physically or mentally) and look for information not fitting the picture of the situation, as though freshly entering the room. Using the aforementioned 10-for-10 principle (CRM key principle 5) can be helpful by actively involving all team members and facilitating other ideas, diagnoses, and objections. Calling for head help from another anesthesia professional unaware of the previous assumptions can break fixation errors; it is best to try not to excessively bias their view of the situation during their incoming briefing. Remember that the burden of proof is on you. For every abnormality you must assume that the patient is not OK until you satisfy yourself otherwise. Similarly, you must assume that any abnormality represents the worst possible diagnosis until you can determine what is actually going on.

Cross and Double Check—Never Assume Anything (CRM Key Point 10). Cross checking and double checking are error-reduction strategies. Cross checking means correlating information from different sources. For example, there are often three independent sources of information on the patient's heart rate (electrocardiogram [ECG], pulse oximetry, and blood pressure monitor) and two of cardiac rhythm (ECG and pulse oximetry). Cross checking across people can be useful both for information that depends on human perception (e.g., auscultation) and for determining which actions were or were not completed. Human memory of actions delegated and performed is vulnerable, especially when interruptions have occurred.

Double checking means to verify information and/or equipment if it is very critical or if in doubt. In brief: to *never assume anything.* The more important or vital the information, the more certainty is appropriate. When chosen therapies do not seem to be working an important double check is whether the intended processes are really happening. For example to double check the proper performance of a critical infusion pump means to check its settings, operation, source of power, and the lines and stopcocks from it to the patient.

Another safety strategy using double checking in anesthesia is the *"Stop-before-you-block"* (SB4YB) campaign (for more information, free poster, and implementation package see www.rcoa.ac.uk/standards-of-clinical-practice/wrong-site-block). The "block time out" campaign was initiated by the Nottingham University Hospital in the UK in 2010 and by now has been adopted worldwide (poster see Fig. 6.9). Meanwhile, several extensions to this strategy have been published.[359,360]

PATIENT SAFETY ACTION BOX

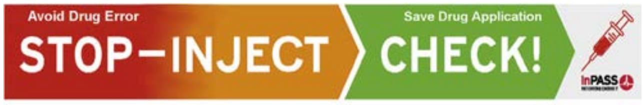
Cross Check and Double Check—Never Assume Anything A related safety strategy is *"Stop-Inject.—Check!"* (Fig. 6.10). In order to prevent medication errors, this strategy is very applicable. Whenever you intend to give an injection, do not inject ("STOP—INJECT") —and at a crucial point of no return think for a few seconds about the injection ("CHECK")—correct any issues—and only then continue with the injection safely. Because if the drug is in, it's in. This strategy is equally applicable to other interventions which cannot be reversed.

Use Cognitive Aids (CRM Key Point 11). The human factors literature demonstrates conclusively that cognitive functions such as memory and arithmetic calculation are vulnerable to error or even complete failure, especially during periods of stress or time pressure. Cognitive aids—such as posters, algorithms, checklists, handbooks, calculators, personal apps, and advice hotlines—come in different forms but serve similar functions. They offload memory and safeguard the correct recall of critical items. Cognitive aids ensure that critical steps are not missed. And they also help ensure the use of current best practices because during a crisis, people sometimes revert to what they originally learned, not what is the latest recommendation. Cognitive aids make knowledge explicit and applicable in the particular situation rather than only being implicit and in someone's brain.

In anesthesiology and emergency care, emergency manuals/crisis checklists, smartphone apps, electronic health record systems, posters, and algorithms are the most common kinds of cognitive aids used. The Internet has become an increasingly useful cognitive aid and may be available on computer terminals, tablets, and smartphones in hospital settings.

The use of cognitive aids is relatively easy and they help to prevent missing critical steps that can be deadly.

In 2003, the US Department of Veterans Affairs National Center for Patient Safety developed an emergency checklist set of 16 serious perioperative emergencies, in concert with the VA Palo Alto/Stanford group, and placed a set of these checklists on plastic laminated sheets in every OR of 105 hospitals. A study of the use of the VA cognitive aids suggested, that they were beneficial to VA anesthesia professionals.[144] Other research has demonstrated that (1) medical and technical performance is better during simulated crisis when a cognitive aid is used [145,361,362] and (2) it can be very helpful to the anesthesia professional leading the team if a reader is present whose job is to read the relevant aid to the team and keep track of whether the relevant tasks have been performed.[363,364]



© Marcus Rall, InPASS

Fig. 6.10 Using stop moments as a valuable patient safety tool for irreversible, critical points of no return, like for example "Stop-Inject. Check!". To avoid unnecessary drug errors, all who intend to inject drugs should take two seconds before injecting a drug ("Stop-Inject"), then confirm ("Check") that the injection is safe to perform (right patient, right medication, right dose, right route, etc....), and only after this short confirmation inject the drug. The figure shows the slogan printed on a sticker that, for example, can be put on medical equipment carts to serve as a daily patient safety memorizer for medical personnel.

For example, Arriaga and colleagues demonstrated in a high-fidelity simulation study that the use of emergency checklists was associated with significant improvement in the management of operating-room crises, suggesting that checklists for use during operating-room crises have the potential to improve care.[145] In the study, 17 operating-room teams from three institutions (one academic medical center, two community hospitals) participated in 106 simulated surgical-crisis scenarios. Each team was randomly assigned to manage half the scenarios with a set of crisis checklists and the remaining scenarios from memory alone. Every team performed better when the crisis checklists were available than when they were not. Failure to adhere to lifesaving processes was less common when checklists were available (6% of steps missed when checklist available vs. 23% when unavailable). 97% of participants reported that they would want to use a checklist if one of these crises occurred during an operation. Further studies concerning this matter have been undertaken.[300,365-368]

Hepner and colleagues give an up-to-date overview of the history, current role, and future directions of cognitive aids in the operating room.[369] Marshall provides a review of the different cognitive aids existing in anesthesia based on a literature review and summarizes recommendations in cognitive aid design, testing, and implementation for the future.[370]

EXAMPLES OF KNOWN COGNITIVE AIGS. There is a growing movement toward the effective use of cognitive aids like checklists and emergency manuals in the operating room, both for routine and crisis situations. Following those movements there have been some recent large checklist implementation processes in health care:

One movement, for example, is the European "Helsinki Declaration on Patient Safety in Anaesthesiology," a shared European opinion of what currently is both worthy and achievable to improve patient safety in anesthesiology.[371] The declaration demands that *"all institutions providing peri-operative anaesthesia care to patients should have protocols [...] for managing [...] difficult/failed intubation, anaphylaxis, local anesthetic toxicity, massive haemorrhage [...]."*

Perhaps the most widely used checklist is the WHO Surgical Safety Checklist that was launched in 2009 by the WHO's World Alliance for Patient Safety accompanying the "Safe Surgery Saves Lives" campaign. A global study[372] showed that the rate of death was 1.5% before the WHO checklist was introduced and declined to 0.8% afterward. Inpatient complications occurred in 11.0% of patients at baseline and in 7.0% after introduction of the WHO checklist. However, there exist several challenges concerning the application of and adherence to the WHO Surgical Safety Checklist, represented by a study that assessed the application attitudes and compliance of the WHO checklist as perceived by anesthesia professionals in Germany.[373] Roughly 60% of participants had knowledge of the theoretical framework. Sign in, patient ID, and surgical site were checked > 95% of the time, allergies addressed in nearly 90%, expected difficult airway in 65%, and availability of blood products by 70%. A total of 85% of participants advocated for the timeout to include all persons present in the operating room, which was the

SIGNS

Some signs may be absent in an anesthetized patient:

1. Hypoxemia, difficulty breathing, tachypnea.
2. Rash/hives.
3. Hypotension (may be severe).
4. Tachycardia.
5. Bronchospasm/wheezing.
6. Increase in peak inspiratory pressure (PIP).
7. Angioedema (potential airway swelling).

1. CALL FOR HELP.
2. CALL FOR CODE CART.
3. INFORM TEAM.
4. CONSIDER PAUSING SURGERY.

1. **If patient becomes pulseless, start CPR, continue epinephrine 1 mg IV boluses and large volume IV fluid.**
2. **Also Go To PEA, event #3.**

RULE OUT

Consider and rule out other causes:

- Pulmonary embolus.
- Myocardial infarction.
- Anesthetic overdose.
- Pneumothorax.
- Hemorrhage.
- Aspiration.

Emergency Manual V3.1 Oct. 2016

ANAPHYLAXIS *continued*

TREATMENT

1. **Discontinue potential allergens:** muscle relaxants, latex, antibiotics, colloids, protamine, blood, contrast, chlorhexidine.
2. **Discontinue volatile anesthetic** if hypotensive. Consider amnestic agent.
3. Increase to **100% O_2**, high flow.
4. **Give IV fluid bolus.** May require many liters!
5. **Give epinephrine IV in escalating doses** every two minutes. Start at 10-100 µg IV and increase dose every 2 minutes until clinical improvement is noted. **Start early epinephrine infusion.** May require large doses > 1 mg.
6. **IF no improvement:** continue treatment, but consider other causes (**Go To Hypotension, event #15, and Hypoxemia, event #16** – consider Differential Diagnoses).
7. Consider **vasopressin** bolus IV or **norepinephrine** infusion.
8. Treat **bronchospasm** with **albuterol** and **epinephrine** (if severe).
9. Consider **additional IV access** and **invasive monitors** (arterial line).
10. If signs of **angioedema**, consider **early intubation** to secure airway.
11. After stable consider **H_1 antagonist** (e.g. Diphenhydramine 25-50 mg IV),H_2 antagonist (e.g. Ranitidine 50 mg IV), and **corticosteroids** (e.g. Methylprednisolone 125 mg IV).

POST EVENT

Consider the following interventions when patient stable:

1. Send serum tryptase level (peaks <60 min post-event).
2. Send serum histamine (peaks <30 min post-event).
3. If the event was severe, consider keeping patient intubated and sedated.
4. Can recur after initial treatment: Consider monitoring patient for 24 hours post-recovery.
5. Refer the patient for postoperative allergy testing.

END

Emergency Manual V3.1 Oct. 2016

Fig. 6.11 Emergency Manual developed by the Stanford Anesthesia Cognitive Aid Group. (A) Front cover of the emergency manual. On the front page it shows the emergency events, thus making it easy to jump to the right page in the case of an emergency. The manual can be hung by its strong metal grommet. Experience shows that clinicians must be familiarized with the manual in advance for optimal use. (B and C) Two pages of the emergency manual for "Anaphylaxis." The content and the layout have been optimized through graphic layout and careful choice of words for easy and ergonomic use in actual operating room emergencies. (Photographs by David Gaba).

case in 57%. A total of 41% stated that the timeout was only performed between anesthetist and surgeon; in 17% of cases, the patient was simultaneously draped and/or surgically scrubbed.

Furthermore there exists a checklist for the significant reduction of catheter-/central-line-related bloodstream infections (CLABSI) in the ICU from Levy and colleagues.[374] And there exist several checklists for handovers and patient-care transition (see also earlier section "Effective Communication and Delegation of Tasks").[295,298,300] A survey[368] on the perception of anesthesia providers from a large academic U.S. institution revealed that printed or electronic aids for patient care transition and shift handoffs in general were valued (61% and 58%, respectively). To prepare for and perform routine anesthesia care, 40% of providers claimed interest in using checklists, however, the interest differed significantly with clinical experience: while both the least and most experienced providers valued aids for routine anesthesia (54% and 50%), only 29% of providers with 2 to 10 years of anesthesia experience claimed interest in using them. Distraction from patient care and decreased efficiency were concerns expressed for the use of routine checklists (27% and 31%, respectively).

Other checklists used especially in anesthesia are the checklist for the anesthesia machine (see earlier section "Pre-use Checkout of Equipment") and emergency checklists or emergency manuals.

EMERGENCY CHECKLISTS/EMERGENCY MANUALS. One known example of a cognitive aid is the use of emergency checklists or emergency manuals, also known by similar terms including emergency response protocols or critical event algorithms. The Stanford Anesthesia Cognitive Aid Group (SACAG) has conducted many years of simulation testing of cognitive aids meant for real-time intraoperative use,[362,363] with increasing levels of optimization through graphic design. SACAG has produced the *Emergency Manual: Cognitive Aids for Perioperative Critical Events ("Stanford Emergency Manual")* (at the time of this writing in version 3.1, see Fig. 6.11). An earlier version of the emergency manual was published as an appendix in the textbook "Manual of Clinical Anesthesiology."[375] In 2013 these cognitive aids were placed in all anesthetizing locations in the Stanford family of teaching hospitals.

The *Stanford Emergency Manual* is available free electronically throughout the world as a downloadable portable document format (PDF) file under a Creative Commons Attribution; Non-Commercial; No-Derivatives License, allowing free non-commercial use of the document as is, without unauthorized modifications, and with attribution of the author (emergencymanual.stanford.edu). Users are able to choose to print out the *Emergency Manual* locally or using any commercial printer; instructions are given on choices of printing paper (e.g., nonflammable and able to be wiped with disinfectant), binding, and placement in perioperative patient care settings.

An equally well-known emergency checklist was developed by the Ariadne Laboratory affiliated with the Brigham and Women's Hospital; it is also freely available and widely disseminated. The Society for Pediatric Anesthesia has a web-based and iPhone app emergency manual that is widely used in that subspecialty arena. A commercially available anesthesia crisis manual designed as a book was published in 2011 by David Borshoff with support of both the European and Australian Societies of Anesthesiology (for details, see www.theacm.com.au). The textbook *Crisis Management in Anesthesiology* while not optimized for real-time use, can also be used in real-time and contains a rather large number (99) of perioperative events.

A recent study compared the impact of paper versus electronic cognitive aids in a simulation-based study, suggesting that the mode of information does not affect performance.[376] The movement for the dissemination and use of such cognitive aids is growing. An Emergency

Manual Implementation Collaborative (EMIC) has been started, bringing together several leading centers in this arena to facilitate the development, testing, dissemination, adoption, and use of these resources. The most recent publications of the Collaborative emphasize the importance for implementation institutions to not only provide cognitive aids such as emergency manuals in accessible places, but also incorporate training mechanisms to increase clinicians' awareness, familiarity, cultural acceptance, and planned clinical use.[377] An implementation toolkit is provided by the Collaborative free of charge (www.implementingemergencychecklists.org/). The EMIC website provides links to obtain many of the available emergency manuals, most of which are non-commercial and free to download.

Collectively across all the relevant emergency cognitive aids for anesthesiology it is believed [DG] that as of late 2018 on the order of 400,000 have been downloaded or disseminated.

Conflicting data concerning the effectiveness of cognitive aids as described in the literature do not necessarily suggest that there is no benefit but suggest that the success of those tools requires complex cultural and organizational change efforts, not just providing the cognitive aid in perioperative settings. In research where no difference was found, the cognitive aids are almost always found to have been introduced without education (an approach termed "print and plunk" by experts on such aids) or to have flaws in their physical design.[370] In 2013 multiple papers and editorials in a single issue of *Anesthesia and Analgesia* discussed a number of important issues about cognitive aids and their implementation.[370,378-381] In the article "Cognitive aids: Time for a change?," Jenkins [382] among other things, draws attention to the fact that besides having checklists ready to use in OR, using them during OR team training for common emergencies would seem a logical next step.

The key elements of the successful implementation of cognitive aids is (1) a culture that embraces cognitive aids not as a sign of clinical incompetence, but as a tool to improve care (see later section on "Safety Culture"); (2) an organizational implementation process like, for example, suggested emergency checklist implementation toolkit (www.implementingemergencychecklists.org); and (3) a proper checklist development and design. Several publications give an overview of the challenges associated with development and implementation of checklists and cognitive aids in general.[383-390]

Reevaluate Repeatedly—Apply the 10-Seconds-for-10-Minutes Principle (CRM Key Point 12). Anesthesia in critical situations is a very dynamic activity. What is correct now may be wrong in the next minute. Some parameters may change slowly over time, and subtle changes are especially difficult to perceive. Therefore, it is critically important to perform a repeated reevaluation of the patient. Reevaluation describes the continual process of assessing the situation and updating one's individual, and at certain stages also the team's, mental model of the situation.

The process of continually reevaluating in order to update the assessment of the situation and monitoring the efficacy of chosen actions is a major part of situation awareness. No crisis manager can be certain of success at any stage in the event. It is crucial to keep thinking ahead (anticipate and plan, CRM principle 2). Do not assume that anything about the situation is certain—double-check all critical items (CRM principle 10). Trend monitoring can be helpful to detect slow but insidious changes.

Questions that should be raised repeatedly to maintain situation awareness and to check whether one is still treating the most serious problem most effectively include:

- Was the initial assessment of the situation or diagnosis correct?
- Did the actions have any effect?
- Is the problem getting better, or is it getting worse?
- Does the patient have any side effects resulting from previous actions?
- Are there any new problems or other problems that were missed before?
- What further developments can be expected in the (near) future?

One way to reevaluate the situation is the regular application of the 10-seconds-for-10-minutes principle at specific stages during the treatment of a crisis (see Fig. 6.8).

Use Good Teamwork—Coordinate With and Support Others (CRM Key Point 13). Teamwork is a very complex topic. But research demonstrates that quality of teamwork influences clinical performance in anesthesia.[326] Some of the principles of teamwork have already been introduced earlier (see section "Teamwork"). Key principles of teamwork in dynamic situations have been delineated, especially in the work of Eduardo Salas, Nancy Cooke, and colleagues.[391-395] Good teamwork depends on different attitudes and characteristics, some of which were already discussed in CRM principle 4, Exercise Leadership and Followership with Assertiveness, and CRM principle 7, Communicate Effectively—Speak Up.

PATIENT SAFETY ACTION BOX

Implement Principles of Good Teamwork—Coordinate With and Support Others Dream teams are made, not born. Dream teams support each other continuously, with everybody looking after each other in a professional manner, the safety and well-being of the patient being highest priority. In contrast to a widespread opinion, good teamwork does not depend on team members liking each other (although it probably helps). Do all players of champion sports teams like each other, or all the time? Probably not. Nevertheless, they function as a high-performing team because they share the common goal to win. Patients are depending on perioperative personnel to be part of a team with emotionless professionalism, using principles of good teamwork, regardless of their personal affinities.

Coordination within a team ideally begins when it gathers. If all members know about the tasks to be done and their roles during these tasks (briefing, see also CRM principle 7), coordination is easy. Short briefings at the beginning of certain tasks as well as short debriefings afterward are common in other complex and dynamic domains, such as aviation, and they are becoming more common in health care. Research in health care indicates that they seem worth the time spent.[217,328] During the acute phase of a crisis, it is valuable to spend a small amount of time to coordinate the team's activities (see e.g., 10-for-10 principle CRM key point 5). Information sharing in teams is important to team performance, cohesion, decision satisfaction, and knowledge integration.[355]

PATIENT SAFETY ACTION BOX

Surgeons are a key part of the team. Sometimes anesthesia professionals act as though they have only two options in dealing with surgeons when a problem occurs—keep quiet or demand immediate cessation of surgery. Actually there are many options (see also: Communicate Effectively) for coordinating activities and concerns. You should notify the surgeons and nurses of ongoing problems and concisely convey to them the nature of the problem, what you'd like them to do (or not do), and the immediate plan. Conversely, you should be prepared to help the surgeons or nurses in any reasonable way when they encounter problems, as long as you can also maintain safe assessment of the patient and control of the anesthetic course.

Allocate Attention Wisely (CRM Key Point 14). As described earlier, several performance-shaping factors (see section on "performance-shaping factors") and hazardous attitudes (see "Attitudes of Professionals as a Crucial Part of Human Performance and Patient Safety", and Table 6.3) can globally degrade your vigilance. However, there are other factors that can specifically degrade your vigilance whenever they exist in a case: one is distractions and interruptions (see sections on "Interruptions and Distractions"). The other is high task load (see section "Performance as Related to Task Density").

Referring again to the core cognitive process model of the anesthesia professional introduced earlier (see earlier section), empiric studies have clearly demonstrated that attention sharing is needed among cognitive levels, among tasks, and often among problems. The intensive demands on the anesthesia professional's attention could easily swamp the available mental resources. Human attention is very limited, and multitasking as well as multiplexing may become very difficult and unsuccessful in a stressful situation.

Attention must be dynamically allocated where it is needed by a dynamic process of constantly prioritizing the tasks requiring your attention. One should handle critical items quickly and leave the less critical problems for when the patient's status has been stabilized. On the other hand when the task load is low, one should deal even with minor problems because they might otherwise evolve to something more significant. One can also use times when the workload is low to prepare for upcoming high workload periods, such as emergence from anesthesia or termination of cardiopulmonary bypass.

Another way to allocate attention is to develop rhythms and scan patterns. For example, always asking questions during the preoperative evaluation in the same sequence makes it less likely to forget items. The ABC mnemonic that equals airway, breathing, and circulation (now CAB mnemonic per U.S. American Heart Association guidelines) is another example that is based on this principle. Other strategies include alternating between focusing on details and focusing on the big picture, and offloading certain responsibilities, tasks, or information streams to other qualified team members (CRM principle 5), with periodic update to the team leader about the situation (CRM principle 13).

Set Priorities Dynamically (CRM Key Point 15). Dynamic situations demand dynamically changing decisions and actions based on new information and constant reevaluation (CRM principle 12). What was not a right move at one time may become the right move at another. In addition, having one solution to an obvious problem does not guarantee that it is the best solution or that only one problem exists. Some goals are always of the highest priority—ensuring adequate oxygenation and perfusion of critical organs being the most crucial—and can never be neglected. In order for team members to understand changing priorities of the team leader, it is important to communicate dynamic priorities effectively (CRM principle 7) and to support each other the best way possible as a team (CRM principle 4 and 13). Sometimes people stick to their first decisions and actions (CRM principle 9).

Evidence for the Benefit of Crisis Resource Management and Other Human-Factor-Related Team Training Curricula

Improvements Following Implementation of Crisis Resource Management. Recently several studies show evidence that CRM training improves patient safety and patient outcomes. In health care organizations, implementation of programs that deal with the concepts of CRM/NTS have been associated with many improvements following their implementation:

- increased provider satisfaction
- improved safety culture and a heightened culture of teamwork[43]
- increased clinical team performance[396]
- decreased room turnover time[397]
- increased percentage of on-time first case starts[42,397]
- decreased preoperative delays, handoff issues, and equipment issues[42]
- improved patient willingness to recommend[397]
- a decrease in medication and transfusion errors[398]
- increased antibiotic prophylaxis compliance[42]
- an increase of efficiency for clinical processes for multidisciplinary trauma teams[399]
- decreased mortality and morbidity[42,400]

Neily and colleagues[42] investigated in a retrospective study including nearly 182.500 sampled procedures whether there exists an association between a CRM-based team training program and surgical outcomes on a national level. The authors showed an 18% reduction in annual mortality compared with a 7% decrease among non-training facilities.

Haerkens and colleagues[5] introduced CRM successfully in the ICU, with data indicating an association between

CRM implementation and the reduction in serious complications and mortality in critically ill patients. The prospective 3-year cohort study was performed in a 32-bed ICU, admitting 2500 to 3000 patients yearly. At the end of the baseline year, all ICU personnel received a 2-day CRM training in small teams, followed by one year of implementation phase. The third year was defined as the clinical effect year. All 7271 patients admitted to the ICU in the study period were included. The ICU complication rate declined from 67.1/1000 patients to 50.9/1000 patients. The incidence of cardiac arrests decreased from 9.2/1000 patients to 3.5/1000 patients, while CPR success rate increased from 19% to 67%. The standardized mortality ratio decreased from 0.72 to 0.60 in the post-implementation year.

Cost-benefit Analysis of Crisis Resource Management Programs. Moffatt-Bruce and colleagues[41] published an innovative study, not only reporting that the implementation of a CRM program at an academic medical center resulted in a 26% reduction in observed relative to expected events, but also evaluating the program's costs and the return on investment. Costs included training, programmatic fixed costs, time away from work, and leadership time. Cost savings were calculated based on the reduction in avoidable adverse events and cost estimates from the literature. Over a 3-year period, roughly 3000 health system employees across 12 areas were trained, costing $3.6 million. Savings ranged from a conservative estimate of $12.6 million to as much as $28.0 million. Therefore, the study presented an overall return on investment for CRM training in the range of $9.1 to $24.4 million, concluding that CRM presents a financially viable way to systematically organize for quality improvement. This study demonstrates that CRM training not only improves patient outcomes (see above) but is also very cost efficient.

Other Curricula for Team Training: TeamSTEPPS and Clinical Team Training

By now, many different types of training strategies fall under the umbrella of team training in medicine, encompassing a broad range of learning and development strategies, methods, and teamwork competencies. Although each is unique in some aspects many of the principles advocated and behaviors taught are similar, and all draw ultimately from the same pool of underlying literature and experience.[401-408] The adaptation of aviation CRM to health care was first described at length at the beginning in the early 1990s.[348] Another team training curriculum, called TeamSTEPPS, was introduced in 2006 and revised in 2015. TeamSTEPPS originated from work done by the U.S. military and was adapted for health care by the U.S. Agency for Healthcare Research and Quality. The U.S. Department of Veterans Affairs introduced its MTT curriculum (later renamed Clinical Team Training, CTT) in 2007.

In the review of Weaver and colleagues,[409] 9 of the 26 studies reviewed used some form of CRM intervention, 7 reported using components of the TeamSTEPPS curriculum, and 3 studies used VA MTT. Seven studies reported using other team-training curriculums. Another current review is that of Marlow and colleagues.[410]

TeamSTEPPS. The TeamSTEPPS curriculum (Team Strategies and Tools to Enhance Performance and Patient Safety)[411,412] is an evidence-based framework that addresses aspects of the following five key elements: team structure, leadership, situation monitoring/mutual performance monitoring, mutual support/back-up behavior, and communication. For implementation, it involves three continuous organizational phases: (1) assessment; (2) planning, training, implementation; and (3) sustainment. The program consists of multiple, explicit team strategies for each of the above mentioned key elements and it provides a source for ready-to-use materials, monthly webinars, as well as a training curriculum (for details see www.ahrq.gov/teamstepps/index.html). This way the program is intended to be fully or partially implemented in an organizational structure as a holistic organizational safety intervention, composed of several explicit safety strategies. The TeamSTEPPS curriculum is designed for health care professionals in general over a wide set of clinical domains. However, health care professionals working in dynamic arenas of high intrinsic risk, like for example anesthesia, intensive care medicine, emergency medicine, etc., face a cognitive and teamwork environment different from many other medical domains.

Clinical/Medical Team Training. The Clinical Team Training program (CTT - formerly named VA M (medical) TT)[413] of the Veterans Affairs National Center for Patient Safety, originally was a classroom-based CRM training program. However, as the program evolved, simulation-based training came to be a crucial part of the currciulum with multidisciplinary on-site training with integrated simulation conducted by experienced faculty.[414] In the CTT program, principles of aviation's crew resource management (CRM) are introduced in a clinical context to model specific applications in the health care environment. The preparation stage requires two months, top leadership engagement being a crucial part in the concept. For initiation, learning sessions are carried out over two days. The learning session is a one-day session delivered twice to increase attendance from clinical units that cannot be closed for training. Implementation is carried out over six months following the learning sessions, and accompanied by coaching and monitoring of unit-based performance outcomes over 12 months.

In our senior author's [DG] view the key difference between TeamSTEPPS and the (A)CRM approach (see earlier relevant section) is the high focus of TeamSTEPPS on very concrete and relevant behaviors (e.g., SBAR, CUS words, two-challenge rule), whereas (A)CRM addresses a broader set of issues, some of which can encompass the particular TeamSTEPPS behaviors. However, TeamSTEPPS does not address directly the components of dynamic decision making of the individual or of some of the more generic issues of team management and teamwork (e.g., distribution of workload, mobilizing and using resources). Some implementations of TeamSTEPPS may miss the forest for the trees. The focus on concrete behaviors has the benefit of giving a wide variety of personnel specific actions they can practice and then perform in daily work. But the downside is that a variety of complex issues of clinical work and of teamwork may be rarely addressed, if at all.

Actually, it seems evident that all of these curricula, and others, are really complementary approaches to similar issues, drawing from the same underlying principles and practices. No single one of them is demonstrably superior to the other, and hybrids combining two or more of them are possible. TeamSTEPPS is popular in part because it is intended to be neutral as to clinical arena or position in the hierarchy and thus is widely applicable, lending itself to organization-wide implementation as described above. It was formulated and disseminated by the U.S. government's Agency for Healthcare Research and Quality, based on the work of internationally acknowledged experts on teamwork (albeit predominantly from non-medical domains). AHRQ provided a free extensive toolkit for TeamSTEPPS implementation. In contrast (A)CRM does not claim to be widely applicable, neutral as to clinical context, or requiring substantial analysis of or implementation by a clinical organization. It is popular especially in dynamic domains of high intrinsic risk analogous to the original one of anesthesiology. While it is successfully used with interprofessional groups in those domains, it is often aimed at physicians as team leaders. Dissemination of (A)CRM was facilitated by its long-standing existence (begun in 1990 and first described in the literature in 1992), publications on extensions into non-anesthesia domains, and an influential textbook (Crisis Management in Anesthesiology) in print via two editions since 1994.

Further Medical Team Training Programs. Besides these three rather well known team-training programs, there are multiple other team training programs, including Team Performance Plus (TPP), Team Oriented Medical Simulation (TOMS), LifeWings/Dynamic Outcomes Management (DOM), Triad for Optimal Patient Safety (TOPS), MedTeams, and Medical Team Management (MTM). They are mentioned for completeness, but for further details the reader is referred to the summary report of the Canadian Patient Safety Foundation[415] and further literature.

Patient Safety on the Organizational Level

In the following part the authors consider the organizational and systems aspects of human performance in anesthesia care and patient safety. Only the organization can sustain the systematic search for and implementation of cross-cutting and practical solutions for front-line patient care. An extensive overview of organizational aspects of patient safety is given by Charles Vincent in the second edition of his book *Patient Safety*.[9]

Organizations should strive to make it easy for clinicians to follow safety-related processes, essentially turning self-interest to work for patient interest. As pointed out by Reason,[123] as well as by Cook, Woods, and McDonald,[122] what goes on in the operational domain of frontline medicine (the so-called sharp end) is extensively shaped by the organizational and managerial environment in which it is embedded (the so-called blunt end). Of course every level has its own sharp end of deliverables and its blunt end of higher influences. For example, the hospital CEO makes policy and direction and is thus the blunt end for everyone else, but is in turn, shaped by regulators, funders, or patient advocacy groups, etc., constituting the CEO's blunt end.

Ideally, senior management commits not only in spirit but also in deed to patient safety as a primary goal. It encourages individuals and teams to fully engage in system-wide patient safety strategies and to trigger change themselves. Management and managers can do this first by changing their own behavior and that of the team, second by educating and persuading others about key changes, and third by searching for and identifying systems issues and pressing for their resolution.

The upcoming sections address (1) the basic concepts of systematic approaches (system thinking) to patient safety and human performance on the organizational level; (2) four organizational patient safety elements for health care derived from high-reliability organization theory (HROT); and (3) important strategies for organizational implementation of these concepts and principles.

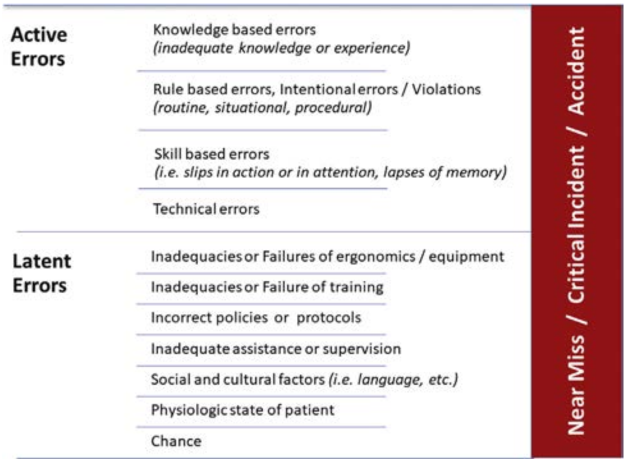
SYSTEMS THINKING

To fully understand many issues in patient safety a broad systems perspective is needed. The actions and failures of individuals and teams usually play a central role, but their thinking and behavior is strongly influenced and constrained by their working environment and by wider organizational processes. The next sections provide systems thinking fundamentals, exploring (1) the definition of human failure and human error; (2) the evolution of accidents and adverse advents in relation to errors; (3) the concepts of hindsight bias and outcome bias as pitfalls in understanding events; (4) three prominent system organizational safety models: normal accident theory (NAT), HROT, and Safety-I/Safety-II; and (5) related concepts of resilience, uncertainty management, and normalization of deviance. More literature for further in-depth engagement with organizational approaches to human performance and patient safety are, for example, the works of René Alamberti, Sidney Dekker, Nancy Leveson, Richard Cook, David D. Woods, Erik Hollnagel, Jens Rasmussen, James Reason, Scott Sagan, Karl Weick, and Kathleen Sutcliffe.

Human Failure: Human Error and Violations

Human error has been conceptualized and investigated for a long time, initially by cataloguing errors and attempting to determine if the myriads of errors could be traced to a small set of causal mechanisms.[132,416] More recently the role of context for understanding error pathways and prevention has become prominent, while research in cognitive neuroscience has contributed to explaining individual vulnerabilities. [417]

Categorization of Human Failure. Different ways to categorize human failure and human error exist. Human failure in general can be categorized into two main types[418]: (1) human error, as an unintentional action



Active Errors
Knowledge based errors
(inadequate knowledge or experience)
Rule based errors, Intentional errors / Violations
(routine, situational, procedural)
Skill based errors
(i.e. slips in action or in attention, lapses of memory)
Technical errors
Latent Errors
Inadequacies or Failures of ergonomics / equipment
Inadequacies or Failure of training
Incorrect policies or protocols
Inadequate assistance or supervision
Social and cultural factors (i.e. language, etc.)
Physiologic state of patient
Chance
Near Miss / Critical Incident / Accident

Fig. 6.12 Active and Latent Human Errors. Derived and adapted from the publication *Catalogue of human error* by Arnstein[419] and Rasmussen's performance levels.[420] Skill-based errors, which incorporate slips and lapses, relate to errors in conscious and subconscious (automatic) cognition. They are also summarized under the term "execution errors." Rule- and knowledge-based errors are summarized under the term "planning errors" or "mistakes." For further information see text.

or decision and (2) violations, as an intentional failure, deliberately doing the wrong thing. Derived and adapted from the error models of Arnstein,[419] Norman,[112] and Rasmussen,[420] human failure can be classified as follows (Fig. 6.12): (a) *Active errors*, including knowledge-based errors, skill-based errors, and rule-based errors (violations). (b) *Latent errors*, including, for example, failure of equipment or ergonomics, incorrect policies/protocols, inadequate training/supervision/assistance, social/cultural factors, etc.

Active Errors

Skill-based errors. Those errors incorporate slips (action not as intended) and lapses of memory (forgetting to do something) and relate to errors in conscious and subconscious (automatic) cognition. They are summarized under the term execution errors. Norman has described five types of skill-based errors[112]:

- *capture error*: a common action taking over from the one intended (e.g., force of habit)
- *description error*: performing correct action on wrong target (e.g., flipping wrong switch)
- *memory error*: forgetting an item in a sequence
- *sequence error*: performing an action out of sequence from other actions
- *mode error*: actions appropriate for one mode of operation but incorrect in another mode

Mode errors are possible with simple devices but they are becoming even more frequent with the increased use of computer-based equipment.[86] An example in anesthesiology of a mechanical mode error is the bag/ventilator selector valve in the anesthesia breathing circuit, which selects between two modes of ventilation. Failing to activate the ventilator when in the ventilator mode can be catastrophic. Newer machines may activate the ventilator automatically when ventilator mode is chosen. Mode errors can also occur with monitoring or drug delivery devices if they assign different functions to the same displays or switches depending on the mode of operation selected.

Particularly dangerous slips of execution can be addressed through the use of engineered safety devices that physically prevent incorrect actions.[59] For example, newer anesthesia machines have interlocks that physically prevent the simultaneous administration of more than one volatile anesthetic. Other interlocks physically prevent the selection of a gas mixture containing less than 21% oxygen. However, all this has come at a price, not only in terms of money, but also in terms of complexity and the introduction of new failure mechanisms.

RULE- AND KNOWLEDGE-BASED ERRORS. Those errors (making an intentional decision that is wrong) are summarized by the term planning errors or mistakes. Additionally, three further forms of error are described as fixation errors (see section "Prevent and Manage Fixation Errors [CRM Key Point 9]").[109] These may be seen as cognitive tunnel vision.

Latent Errors. James Reason, who literally wrote the book on human error, introduced the concept of latent errors, for which he also used the metaphor of resident pathogens: "*... whose adverse consequences may lie dormant within the system for a long time, only becoming evident when they combine with other factors to breach the system's defenses. [They are] most likely to be spawned by those whose activities are removed in both time and space from the direct control interface: designers, high-level decision makers, construction workers, managers and maintenance personnel*" (p. 173).[59]

Latent errors evolve from latent threats like organizational culture, professional culture, scheduling, management policies and decisions, organizational processes, etc.

This threat and error model was articulated by the aviation-oriented psychologist Robert Helmreich, distinguishing between (1) latent threats (national and organizational culture, professional culture, scheduling and policies, management decisions, and organizational processes), (2) individual threats (team factors, patient factors, organizational factors, environmental factors, and individual staff factors), and (3) management threats (error management strategies and countermeasures).[421]

A variety of latent failures/threats/errors can exist in the anesthesia environment.[14] They may include such issues as how surgical cases are booked, how cases are assigned to specific anesthesia professionals, what provisions are made for preoperative evaluation of outpatients, and what relative priority is given to rapid turnover between cases or avoiding cancellation of cases as opposed to avoiding risk.[422] Latent errors can also result from the design of anesthesia equipment and its user interfaces, which in some cases lead clinicians to err or are unforgiving of errors. Manufacturing defects and routine maintenance failures are also types of latent failure, as well as training, supervision, etc.

Evolution and Investigation of Accidents: One Error is not the Cause of an Accident

Traditionally, one speaks of errors arising in decisions and actions that lead to a mishap or an accident possibly with patient harm. However, the term error is increasingly considered inappropriate as it typically jumps to

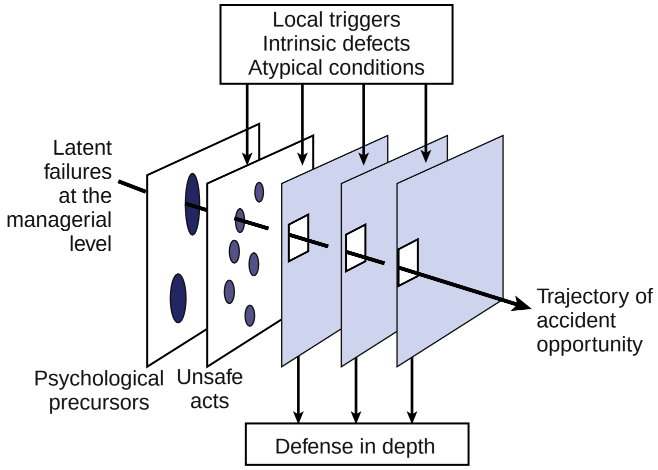


Fig. 6.13 James Reason's model of the causation of accidents. The model shows the different "defense shields" an organization possesses. Those shields prevent accidents at different levels. But each shield has weak spots, envisioned by the holes in the different shields. As work and the work environment in health care are dynamic, the diagram should be envisioned as being three-dimensional and also dynamic—with the shields moving around and holes opening and closing. If now, for example, latent failures at the managerial level combine with psychological precursors and active event triggers at the operational level, an accident sequence can be initiated. As long as there is no direct trajectory through the shields, the accident sequences are trapped at one or more defensive shields of the system. But if there develops a direct trajectory, the unforeseen combination of organizational or performance failures with latent errors and triggers may lead to breach the system's defenses and allow the accident to take place. This model is also known as Reason's "Swiss Cheese Model." Charles Vincent adapted Reason's model and published an extended model named "Organizational Accident Model."[9] (Figure redrawn from Reason JT. *Human Error*. Cambridge: Cambridge University Press; 1990.)

conclusions of attribution and blame. Current organizational accident models indicate that errors are usually the consequence of a combination of several underlying factors and conditions (i.e., root causes and contributing factors) that yield an event (Fig. 6.13).[59] Vincent and colleagues published a framework of contributory factors, called the seven levels of safety.[423] In their work, the error-producing conditions and organizational factors are classified as: patient factors, task factors, staff and team factors, work environment factors, organizational/management factors, and institutional context factors. This classification is used in the London Protocol,[424] an investigation and analysis tool for the processing of incident reports.

Human error—a window to the system. Human error can be seen as a window onto the usually hidden dynamics of the work system.[9,425,426] Sidney Dekker, pilot and human error expert, wrote:

> *"You can see human error as the cause of a mishap. In this case, 'human error' under whatever label—loss of situation awareness, procedural violation, regulatory shortcomings, managerial deficiencies—is the conclusion of your effort to understand error. [Or] you can see human error as the symptom of deeper trouble. In this case, human error is the starting point for your efforts. Finding 'errors' is only the beginning. You will probe how human error is systematically connected to features of people's tools, tasks, and operational/organizational environment." (p. xi)*[427]

Whereas the first statement describes the old view on human error (person approach), the latter describes the new view on human error (system approach), albeit itself being a few decades old.[428] The new view focuses not on finding where people went wrong but rather to understand what triggered their assessment, actions, and decisions at the time, given the circumstances that surrounded them. Errors and violations should be addressed on a systems level as opposed to just with the individual(s) involved.

Investigation. Investigation of untoward events (see later section on "Critical Incident Reporting") should address both latent and active failures, and both the organizational/managerial environment and the operational domain. Focusing primarily on active failures may miss the fact that frontline personnel are often victims of the system in a Catch-22 situation, typically pushed to maximize production while admonished to be safe. Condemning only their actions—and not the latent pressures and conditions under which they work—will make them defensive and uncooperative. Cook and Woods pointed out that if one looks at the chain of events in an accident sequence, one can always find a failure on the part of an operator.[429] If the analysis stops at this point, the operator may be wrongly blamed in part or in whole while the real systemic root causes may not be detected; they will remain to cause other adverse event chains in the future (see later section on "Critical Incident Reporting").

PATIENT SAFETY ACTION BOX

Admonishing personnel to *"Try harder!"/Be more careful!"/" Next time you have to pay more attention!"* is known to be a fruitless way to address safety issues; such situations need explicit practical changes in the way the work is being performed and organized that make it easier to comply.

Evaluation of Errors and Accidents: Hindsight Bias—"I knew it all Along" and Outcome Bias—"No Harm no Foul"

Hindsight Bias. The psychological phenomenon called hindsight bias plays an important role in the attribution of causes to accidents and adverse events. The bias is sometimes called *"Monday morning quarterbacking"* or the *"I knew-it-all-along effect."* After an event, it seems easy to conclude what went wrong, what the people involved did or did not do, what information turned out to be critical, and to recognize exactly the kind of harm that should have been foreseen or prevented: "*There is almost no human action or decision that cannot be made to look flawed and less sensible in the misleading light of hindsight. It is essential that the critic should keep himself constantly aware of that fact*" (p. 147).[430] Similarly Leveson wrote "*Before the event [accident], such insight is difficult and, perhaps, impossible*" (p. 38).[12] Hindsight bias, which typically underestimates complexity and cannot represent a comprehensive analysis of what and how factors interacted to lead to an error or accident, is linked to the old view of human error presented earlier. Hindsight bias still is insidious and very hard to overcome, bearing the danger to impair organizational learning, to contribute to personal overconfidence, and to even to misjudge reasonable actions as medical malpractice.[431,432]

Outcome Bias. A related bias is the outcome bias, sometimes—when the outcome is good—using the sports metaphor of "no harm no foul."[431] It occurs when the judgment of a situation is made dependent on the outcome (known only in hindsight) rather than on the decision-making process itself. Harsher judgments are often made when an outcome is bad, becoming even harsher depending on the severity.[433]

PATIENT SAFETY ACTION BOX

When trying to make sense of events it is important to ask *"Why"* or *"How come?,"* to fully understand the problem and the thought processes in the moment of those involved. Jumping to conclusions prematurely can lead to solutions that are inappropriate or ineffective because they do not address the actual roots of the problem.

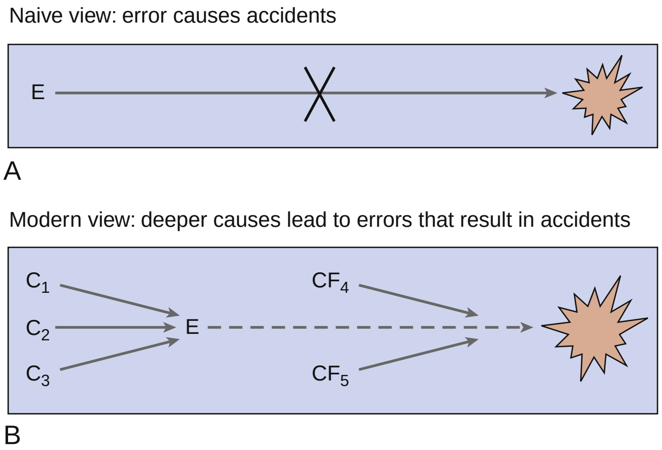
System Error Models: Normal Accident Theory and High Reliability Organization Theory

Several schools of thought about organizational safety in highly hazardous activities exist. Two complementary theories, Normal Accident Theory (NAT) and High Reliability Organization Theory (HROT), have dominated the discussion of system safety in many domains and have been applied to health care with increasing frequency since the 1980s.[59,123,434] NAT was originally promulgated by the sociologist Charles Perrow in the wake of the Three Mile Island (Pennsylvania) nuclear accident.[54] It has been applied by him and others to such diverse fields as commercial aviation, maritime transport, and the handling of nuclear weapons. A different theory, HROT, was put forth initially by Todd LaPorte, Gene Rochlin, and Karlene Roberts,[435-437] and later Karl Weick and Kathleen Sutcliffe.[438-441] It has been applied to diverse domains, including aircraft carrier flight decks, offshore oil platforms, air traffic control, nuclear power production, and the financial transaction industry. Both NAT and HROT agree that interactive complexity and tight coupling can lead to a system accident. However, they hold different opinions on whether those system accidents are inevitable or manageable.

In brief, the rather pessimistic view of NAT suggests, that disasters are the unwanted but inevitable (normal) results of complex socio-technical systems one cannot design around; the rather optimistic view of HROT sees disasters as preventable and manageable by certain key design characteristics or response systems of the organization.

A number of comparisons of these theories have been provided, giving an overview of the two theories, their advantages and limitations, and sometimes suggesting approaches that move beyond them.[442-446] Hollnagel and colleagues have promoted another influential error model called resilience engineering,[447-451] which has been compared to HROT by Haavik and colleagues.[452] One can argue that none of the other theories have replaced either NAT or HRO, and nearly all experts now believe that these exist in parallel, each providing a complementary view of the same set of issues.

Normal Accident Theory. NAT focuses primarily on three features of a system: (1) the complexity of interactions in the system, (2) the presence of tight coupling among the system's elements, and (3) the catastrophic potential of the system. Perrow[54] argues that the coexistence of interactive complexity and tight coupling in socio-technological systems leads to unpredictability of interactions and hence system accident is inevitable or normal. NAT suggests that when complexity and tight coupling coexist, abnormal sequences of events can be hidden and have complex or unpredictable consequences. Active errors in the system may not result in an accident only if, they are trapped at some point by the system's multiple layers of checks and defenses (Fig. 6.14; see also Fig. 6.13).



Naive view: error causes accidents
E
A
Modern view: deeper causes lead to errors that result in accidents

C_2
C_3
E
CF_4
CF_5
B

Fig. 6.14 Relationship between errors and adverse events. (A) Errors are the cause of accidents. Rather naïve views see the causes of accidents directly and solely linked to errors (*E*), as errors oftentimes lead directly to the accident. But errors are not the cause of accidents alone. (B) Errors are not the cause of accidents. In the more modern view, errors are one part of a multifactorial environment, when accidents occur. Multiple root causes (*C1, C2, C3*) lead to the error (E). For the most part, in an accident sequence additional contributing factors (*CF4, CF5*) are necessary to allow the error to evolve into an accident, explaining why profound analysis of an accident or incident is necessary in order to prevent similar consequences. (Modified from Rall M, Manster T, Guggenberger H, et al. Patient safety and errors in medicine: development, prevention and analyses of incidents [in German]. *Anesthesiol Intensivmed Notfallmed Schmerzther.* 2001;36:321–330 with permission.)

NAT also proposes that professionals delude themselves by believing that they can perfectly control hazardous activities and forestall disaster all the time. In reality, many of the efforts people make at management and design tend only to increase the opacity and complexity of the system (making more holes in the barriers, Fig. 6.13) thereby increasing the likelihood of accidents. The combination of these factors with normal everyday faults, slips, and incidents provides fertile ground for the occurrence of accidents.

NAT considers safety as one of many competing organizational objectives, but often not of sufficiently high priority. For preventing adverse events, Perrow suggested that attention should be directed at strengthening the recovery pathways by which small events can be properly handled before they evolve into a serious accident. In fact, this suggestion by Perrow in the book *Normal Accidents*—plus the apparent success in commercial aviation—were direct inspirations for Gaba and colleagues to develop simulation-based CRM-oriented training, and to create and disseminate emergency manuals (cognitive aids).

BOX 6.7 Characteristics High Reliability Organizations Hold in Common…[454]

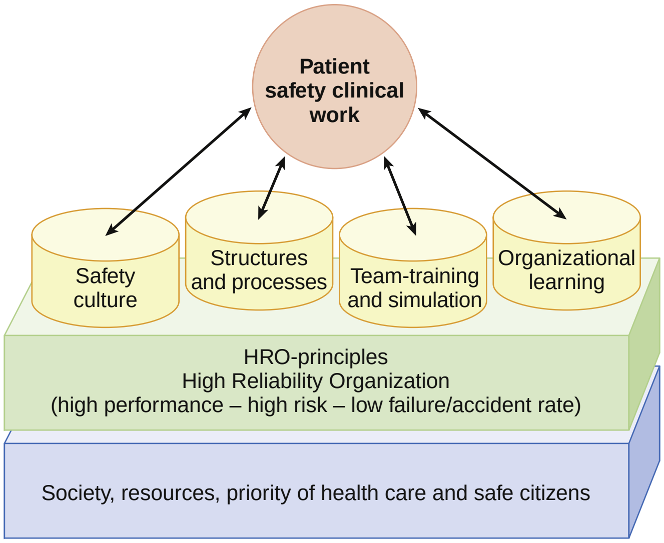
- Hypercomplex environment—extreme variety of components, systems, and levels.
- Tight coupling/interdependent teams—reciprocal interdependence across many units and levels.
- Extreme hierarchical differentiation—multiple levels, each with its own elaborate control and regulating mechanisms.
- Multiple decision makers in complex communication networks—characterized by redundancy in control and information systems.
- Degree of accountability that does not exist in most organizations—substandard performance or deviations from standard procedures meet with severe adverse consequences.
- High frequency of immediate feedback about decisions.
- Compressed time constraints—cycles of major activities are measured in seconds.
- More than one critical outcome that must happen simultaneously—simultaneity signifies both the complexity of operations as well as the inability to withdraw or modify operations decisions.

BOX 6.8 Organizational Strategies[438] that Guide the Thinking of People in High Reliability Organizations:

- Preoccupation with failure
- Reluctance to simplify interpretations
- Sensitivity to (front-line) operations
- Commitment to resilience
- Deference to expertise

High-Reliability Organization Theory. In contrast to these rather pessimistic views of NAT concerning the organizational challenges to safety, HROT suggests that proper organization of people, technology, and processes can handle complex and hazardous activities at acceptable levels of performance.[373,453] In fact, consider the many endeavors in which HROs manage to achieve nearly failure-free results despite high intrinsic risk and high throughput.

Box 6.7 shows the common characteristics of HROs.[454] It is important to note that many organizations display some of these characteristics, but true HROs display them all simultaneously. Box 6.8 shows the organizational safety strategies that guide the thinking of people in an HRO. Although these elements point in the right direction, they remain theoretical if not—in our case—translated to health care, and then embedded into the fabric of an organization's operations. An HRO-based safety strategy tool in the form of a reference sheet is available at no cost from the Institute for Healthcare Improvement (IHI).[455] Fig. 6.15 shows four strategic key elements of HROs, which are explained in more detail in Boxes 6.9 and 6.10 and in the following section.



Patient safety clinical work
Safety culture
Structures and processes
Team-training and simulation
Organizational learning
HRO-principles
High Reliability Organization
(high performance – high risk – low failure/accident rate)
Society, resources, priority of health care and safe citizens

Fig. 6.15 The fundamentals and principles of a high reliability organization.

BOX 6.9 Elements of a Culture of Safety[437,441,454,560]

Values

- Safety is most important goal, overriding production or efficiency
- Preoccupation is with possible "failures," not past "successes"
- Necessary resources/incentives/rewards are provided for optimal safety, not only for optimal production

Beliefs

- Safety must be actively managed
- Processes and routines of care are as (or more) important to safety as individual dedication, skill, or effort
- Openness about safety and errors is essential; learning from normal and adverse events should be thorough

Norms

- Low-ranking personnel raise safety issues and challenge ambiguity regardless of hierarchy or rank
- Calling for help is encouraged and occurs frequently, even by experienced personnel
- Explicit communication is frequent
- The hierarchy is flat—leaders listen to juniors; juniors speak up; and calling for help is routine regardless of rank
- People are rewarded for rationally erring on the side of safety, even when their credible concerns turn out to be wrong

Modified from Weick KE. Organizational culture as a source of high reliability. *Calif Manage Rev*. 1987;29:112–127.

Anesthesiology has traditionally been strong at some elements of HRO, particularly in redundancy and technical safety measures. A movement is growing in anesthesia to implement HRO philosophies and techniques more fully.[456] In fact, anesthesiologists not only have been promoters of the patient safety movement in general but also have been leaders at applying HROT principles to health care. In 2003, the APSF began initiatives in high reliability perioperative health care (see special issue of the *APSF Newsletter*, summer 2003, at www.apsf.org). More recently, HROs have been conceptualized as one of three approaches to safety: ultra-adaptive (which embraces risks, e.g., trauma center), high-reliability (which manages risks, e.g., scheduled surgery), and ultra-safe (which avoids risk, e.g., radiotherapy).[10] Providing anesthesiology to an ASA1 patient is considered between the high-reliability and ultra-safe approach.[10]

BOX 6.10 Key Elements of a High-Reliability Organization in Medicine[437,441,454,560]

Established Culture of Safety (see elements Box 6.9)

Optimal Structures and Procedures

- Decision making rests with those with greatest knowledge or experience about specific issues regardless of rank or job type.
- The unit integrates crews from different departments (e.g., cardiac surgery, cardiac anesthesia, OR nursing, perfusion, ICU) into a coherent clinical team. Teamwork and resiliency are emphasized.
- Formal procedures are in place to maximize transfer of information to all team members before a case (e.g., briefings or time-out procedures).
- Schedules are designed to keep work hours and duty periods at reasonable levels to avoid undue fatigue. Personnel under excessive stress are supported or replaced as needed.
- Standardized procedures, techniques, and equipment are adopted whenever possible so that similar tasks or operations are performed similarly regardless of the personnel involved; conversely, when necessary (in an emergency or adverse event), the team is resilient and responds as needed to the situation without slavish dependence on standard routines.
- The use of preplanned algorithms, checklists, and cognitive aids is actively encouraged.
- Easy access to current information systems is available at all times and all locations.

Training and Practice in Routine Procedures and Simulations

- Debriefings are conducted after each case.
- Nonpunitive assessment instruments are used on a regular basis to provide current feedback and identify elements requiring special training.
- Initial and recurrent simulation-based single-discipline and multidisciplinary training in crew resource management occurs (see Chapter 7).
- Actual clinical crews and teams conduct periodic drills or simulations of critical situations in the real OR, PACU, and ICU.
- Resident training uses a guided curriculum; training goals and the level of responsibility assigned to a resident match the current proficiency level of the trainee with the complexity of the procedure.

Organizational Learning

- Robust mechanisms are in regular use for organizational learning, both prospectively (considering in advance how to optimize protocols and procedures, such as failure mode and analysis of effects) and retrospectively (from analyzing reports of adverse events, near misses, or problems such as root cause analysis).
- Problems are analyzed primarily to determine what can be improved, rather than whom to blame. Altered procedures are assessed and adopted as appropriate. Process changes reflect appropriate analysis.

Safety I and Safety II: Ensuring that as Few Things as Possible go Wrong or that as Many Things as Possible go Right…?

As indicated above, perspectives on safety are changing. In recent years several scientists questioned the definition of safety as the absence of errors. A new view of safety has evolved, defining it as maximizing the ways that work can evolve in a correct way and focusing primarily on why human performance succeeds most often despite myriad challenges. Erik Hollnagel labelled this new approach Safety-II, as opposed to Safety-I, which denotes the traditional approach investigating errors, incidents, and accidents.[457] *"Safety management should therefore move from ensuring that 'as few things as possible go wrong' [Safety-I] to ensuring that 'as many things as possible go right [Safety-II]'"* (p. 4).[458]

The Safety-II approach aims to understand how good performance is actually produced: how people adapt the workflow, their use of devices, and their organization of tasks to achieve good performance even in challenging circumstances. In this regard it is quite similar to HROT. Safety-II also sees successful performance as a learning space:

> *this "…approach assumes that everyday performance variability provides the adaptations that are needed to respond to varying conditions, and hence is the reason why things go right. Humans are consequently seen as a resource necessary for system flexibility and resilience. In Safety-II the purpose of investigations changes to become an understanding of how things usually go right, since that is the basis for explaining how things occasionally go wrong." (p. 4)*[458]

Perhaps the most important new ideas of Safety-I and -II are the analytical character of the models. The focus on positive performance provides a different lens and rather than emphasizing the individual's success it addresses how and why such success occurs. One specific method that Hollnagel[459] describes is functional resonance analysis, which identifies the different pieces of a system and investigates in detail how they interact with each other dynamically. Many phenomena emerge from the interplay of the system parts, but this emergence might not be easy or possible to explain on a causal basis. A detailed description of the Safety-I and Safety-II approach by Hollnagel, Wears, and Braithwaite is available in PDF format online (*"From Safety-I to Safety-II: A White Paper. The Resilient Health Care Net"*).[458]

Resilience and Uncertainty Management: Safety is a Dynamic State, not all Risks can be Eliminated

System safety is not a static property of hospitals and departments; rather it is dynamic, often on short time scales. Even with the implementation of robust patient safety strategies and regulatory regimes, (1) not all risks can be eliminated in the system and (2) safety, even once established, is not omnipresent or infinitely persistent. Whether risk in any setting can credibly be lowered to zero is widely debated. Admitting that risk cannot be prevented while striving to find more appropriate ways of handling adverse occurrences, for example through improving system resilience [447,448] or the ability to manage uncertainties,[460-465] seems appropriate regardless of the theoretical approach. Whereas some system safety methodologies view even a domain's own professionals as unreliable components, the theories of HRO, Safety-I, and Safety-II view people as core elements in creating reliable systems.

Resilience. The term resilience in respect to patient safety is derived from resilience engineering and is an important characteristic of HROs. The introduction to health care was promoted by Hollnagel and colleagues. Resilience describes the intrinsic ability of individuals, teams, and the system to cope with and adjust to new or changing demands and to respond effectively and safely to unforeseen, unpredicted, and unexpected problems or demands as they occur, even after a major mishap or in the presence of continuous stress. A resilient system owns the ability to produce success despite conditions that could easily lead to failure.

Uncertainty Management. Grote argues that *"in order to improve risk management and safety more generally deliberate increases in uncertainty may be beneficial"* (p. 71).[460] Grote furthermore distinguishes two uncertainty paradigms[461]: (1) Uncertainty may be minimized by high levels of standardization, central planning, automation of work/processes, and high levels of specialization with few degrees of freedom for employees (stability). (2) Newer organization theories in contrast stress the need for flexible adaptation in highly uncertain and networked processes, empowering everyone in the organization to cope with uncertainty by providing them with options for action rather than fixed plans and standards. As a consequence, organizations must find a way to balance stability and flexibility as both can mutually enable each other.[466] It sometimes can be worth tolerating some degree of uncertainty—relying on flexible adaptation of intelligent, well-trained personnel and stability by well-functioning systems—rather than to attempt to eradicate every possible uncertainty by standardization. From an HROT perspective's view one could say to standardize where possible (or sensible) while remaining flexible and resilient. Clearly there is a sweet spot between these extremes, although how to achieve that balance remains under debate.[467]

Normalization of Deviance and Flirting with the Margin

Normalization of Deviance. Normalization of deviance is a term first coined by American sociologist Diane Vaughan who conducted a detailed organizational analysis of the Space Shuttle Challenger disaster.[468] The phenomenon occurs when people within an organization become so insensitive to deviant practices or occurrences that do not cause a problem that the practices themselves no longer seem wrong—essentially creating a *"new normal."* Such normalization of deviance emerges insidiously, sometimes over years. Once this happens on a large scale, no one within an organization is able to see the shortcomings in the behavior. They become resistant to suggestions that they are in fact abnormal and deviant, dismissing allegations that *"the emperor has no clothes."* Because disaster indeed does not happen without a number of critical factors lining up, their resistance is reinforced by the continued good outcomes—until a catastrophe occurs. Many have applied these concepts to health care including anesthesiology.[48-50,445] Banja[47] gives an overview of the topic in health care overall and identifies a number of reasons why normalization of deviance occurs in organizations, including:

- The existing rules are considered stupid and inefficient
- Knowledge is imperfect and uneven
- The work itself, along with new technology, can disrupt work behaviors and rule compliance
- "I'm breaking the rule for the good of my patient!"
- "The rules don't apply to me"/"You can trust me"
- Workers are afraid to speak up
- Leadership is unaware of or downplays reports or findings on system problems

Flirting With the Margin. Cook and Rasmussen published two related models to normalization of deviance that can be understood as flirting with the margin.[469] Their so-called dynamic safety model identifies three different states of a system in which an organization can operate (stable systems, unstable systems, stable but high-risk systems). The model points out that the states can be floating, depending on the set of organizational boundaries (i.e., economic, workload, acceptable performance) and the pressures within the system (i.e., management, safety campaigns/culture, staff). Typically the highest economic yield lies near the margin and the system may be pushed toward or even over the marginal boundary that safeguards systems from errors, accidents, and adverse events. The constitutive flirting with the margin model draws attention to the risk that repeated shifts outside the marginal boundary may lead to the original margin being judged as too conservative, resulting in a shift of the marginal boundary (normalization of deviance). When this happens regular operations in a system take place in an already dangerous marginal zone, implying a false sense of safety and raising the probability of accidents.

ACHIEVING HIGH RELIABILTY AND SYSTEM THINKING: FUNDAMENTAL ELEMENTS FOR A SYSTEMATIC SAFETY APPROACH

How can clinical departments and health care institutions transform into a high-reliability organization? Addressing safety at the individual and team level has yielded some useful improvements in health care. However, more comprehensive improvement will require transforming whole organizations. Altering particular care processes is not enough; the work culture needs to be transformed. The AHRQ published a report in 2008—*"Becoming a High Reliability Organization: Operational advice for Hospital Leaders"*—that summarizes the topic in depth.[470]

As displayed in Fig. 6.15, HROs can be characterized essentially by four key structural pillars: (1) creation and sustainment of a culture of safety; (2) global and profound organizational learning, including incident reporting systems (IRS); (3) continuous training of individuals, teams, and work units including the regular use of simulation; and (4) continuous optimization of safety-relevant structures and processes. The four pillars are intended to provide anchor points for systematic organizational improvement. They are explained in more detail in the subsequent sections.

Culture of Safety

Creating a culture of safety is an important element of enhancing patient safety.[471-473] Safety culture is part of the

BOX 6.11 **Key Features of High Reliability Organizations Based on the AHRQ's Definition**[561]

- acknowledgment of the high-risk nature of an organization's activities and the determination to achieve consistently safe operations
- a blame-free environment where individuals are able to report errors or near misses without fear of reprimand or punishment
- encouragement of collaboration across ranks and disciplines to seek solutions to patient safety problems
- organizational commitment of resources to address safety concerns

overall culture of an organization. Opposed to the widely spread culture of blame (also called negative safety culture), the culture of safety is also referred to as the culture of no-blame or is reinforced in its meaning by the expression positive safety culture.

One prominent definition of culture is: "*A pattern of shared basic assumptions learned by a group as it solved its problems of external adaptation and internal integration*" (p.12).[474] More simply, culture is "*the way we do things around here,*" or "*what you do when nobody is looking.*" The Joint Commission defines safety culture as follows: *"Safety culture is the sum of what an organization is and does in the pursuit of safety. [. . .] the product of individual and group beliefs, values, attitudes, perceptions, competencies, and patterns of behavior that determine the organization's commitment to quality and patient safety"* (p. 2).[475]

Edgar Schein described three elements of culture that can be observed: (1) artifacts that are used in the organization (e.g., charts, clothes/uniforms, meetings, rituals), (2) espoused beliefs and values (some measurable in surveys and some by interviews or by watching and listening to everyday work), and (3) underlying assumptions that are so ingrained that they are hardly noticeable any more (e.g., what is meant by a patient vs. a client or partner; by illness vs. health; or by safety vs. quality or outcome). Box 6.9 shows the major elements of a culture of safety based on shared values (what is important), beliefs (how things should work), and norms (the way things work).

The Joint Commission published behaviors that undermine a safety culture and suggests respective countermeasures.[476] Two reviews on the current literature of safety culture are available.[477,478]

A health care HRO's commitment to safety needs to start at the top—with full buy-in from chief executives and boards of directors or trustees and palpably extend through all levels of middle managers and fully into frontline personnel (professionals and others). This commitment encompasses the key features (based on AHRQ's formulation) shown in Box 6.11.

When an organization does not promote a culture of safety, staff members often are unwilling to report adverse events and unsafe conditions because they fear reprisal or from prior experience believe reporting rarely results in change (see later sections "Organizational Learning" and "Incident Reporting").[471]

A variety of techniques have been developed to help organizations create and sustain a safety culture. Some of these address getting senior managers and executives more directly in touch with what is happening at the sharp end of work, by activities such as Patient Safety Leadership Walk-Rounds[479] or Leveraging Frontline Expertise (LFLE).[479,480] Other interventions suggested by the IHI include: designation of a patient safety officer, involvement of patients in safety initiatives, appointment of a safety champion for every unit, safety briefings, and simulation of possible adverse events (see later section on "Periodic Team Training and Simulation Team Training" and Chapter 7).[481] Other widely available guides to address an organization's safety culture come from The American College of Healthcare Executives and IHI/NPSF Lucian Leape Institute[482] and the Joint Commission.[483] It is hard to demonstrate which, if any, of these strategies and techniques are most effective, and it may depend heavily on a variety of local factors in each organization.[484]

It is problematic that, sometimes, safety culture is thought to mean culture of no blame. Safety culture is actually a much broader concept and the notion of no blame or blame-free has widely given way to the concept of a just culture. While no blame is appropriate for many unintended errors, other actions do seem blameworthy and demand individual accountability. A just culture focuses on identifying and addressing systems issues that lead individuals to engage in unsafe behaviors, while maintaining individual accountability by establishing zero tolerance for reckless behavior. It distinguishes between human error (e.g., slips), at-risk behavior (e.g., taking shortcuts), and reckless behavior (e.g., ignoring required safety steps). Gross negligence, behavior violations, and destructive acts are not tolerated.

Nonetheless, unjust cultures of individual blame still appear to be dominant.[476] Khatri and colleagues reported an increased likelihood of a culture of blame in health care organizations that (1) rely predominantly on hierarchical, compliance-based management systems; (2) attach less importance to employee involvement in decision making; and (3) neglect human resource management capabilities to help foster a safety culture.[485]

PATIENT SAFETY ACTION BOX

Mind your language! Ensure that dialogues, interviews, discussions, and reports avoid judgmental or blaming language (e.g., *"You should/could have...," "Why didn't you...?," "Do you think that was a good idea?," "The professional failed to..."*). Instead, use language that encourages systems thinking.[486]

Anesthesiology as a specialty has played a leading role in the attempt to turn the rather predominant culture of blame into a culture of safety—putting safety first and trying to understand how errors, incidents, and adverse events evolve.[11,40,456,487-490]

Measuring Safety Culture. Measuring safety culture is difficult. Strictly speaking, it may only be possible to investigate culture by anthropologic means—embedding ethnographers into the workplace for deep understanding of how work is conducted. This can be supplemented by structured interviews. Such methods are difficult and costly. More frequently safety culture is measured through written surveys of health care personnel. Essentially these measure safety climate—the attitudes of personnel as represented by survey responses. It is difficult to extrapolate from these results to the culture as actually enacted. Nonetheless, surveys are relatively simple and low cost, especially since the advent of online administration of the instruments.

Several validated survey tools are available to measure hospital safety and teamwork safety climates, including, for example, the Patient Safety Culture in Healthcare Organizations (PSCHO),[491-493] the AHRQ Survey on Patient Safety Culture, and the Safety Attitudes Questionnaire (SAQ). Each of the various instruments have a somewhat different focus, and the methods of administration of such surveys can be very important.

Among the issues that influence what can be learned from such surveys are: (a) Who is asked to complete the survey? Is it hospital-wide or just in one or a few work units? Sometimes the work unit is the appropriate unit of analysis but often the target may need to be broader.[494] (b) Are managers and senior leaders sampled in the same fraction as other workers? If so, this will mean that their views will not be well represented because they make up such a small fraction of the overall workforce. Oversampling of important but small populations can compensate for this. (c) Are the surveys truly confidential or anonymous? (d) How are the data interpreted? Looking primarily at the views of the majority of respondents may not be sufficient. If only a modest fraction (the rule of thumb from some experts is about 10% or more) respond in ways antithetical to a culture of safety that may represent a serious lack in its uniformity, and show a problem. For example, elements of the PSCHO survey have been asked also in different surveys of military aviators, acknowledged HRO. The negative safety views almost never were near the 10% level but this was seen substantially more often in the health care population.[495] Teamwork and communication dimensions of safety culture have been significantly related to adverse clinical events.[491,496-498]

Despite the past decade's focus on improving patient safety, most health care organizations are still striving to achieve high-reliability organization status[445,499]—consistently providing high quality care, with substantial load while minimizing adverse events.

In an update of the sentinel event alert from 2009, the Joint Commission 2017 calls again for senior health care leaders to establish a culture of safety within their organizations, use just culture principles to establish transparent and fair policies for addressing errors by clinical personnel in the front lines, and maintain robust structures for analyzing and responding to adverse events. Specific suggested actions include involving hospital boards and patients in safety efforts and making safety performance an explicit part of the evaluation for leaders. Adherence to sentinel event alert recommendations is assessed as part of Joint Commission accreditation surveys.[475]

PATIENT SAFETY ACTION BOX

Mind your attitude! Pursuing a culture of safety oftentimes is about one's attitude and reactions when safety concerns are raised. For example: If a patient's condition is deteriorating and someone else calls the rapid response team (RRT) when you think you might have things under control, don't say *"Why did you call the RRT? It's fine, do you think I'm an idiot?"* Instead it's better to say *"Thanks for calling the RRT—I think I know what's going on and have it under control, but it can't hurt to have them here."* Conversely, when a team arrives, if they find that there is no active crisis, they should not complain (or roll their eyes). Instead they should thank the clinician for calling them and offer to help in any way even though they seem to have things well in hand. In health care, one sometimes rewards people verbally for a good pickup, noticing something that is clearly of importance to the patient's care. Yet one rarely rewards people for raising their credible concerns when they turn out not to be an issue. Providing such rewards regardless of outcome will strengthen the safety culture and foster the desired speaking up.

Organizational Learning

An important strategy for improving patient safety and a core content of HROs is organizational learning. Organizational learning *"is defined as the process of creating and applying valid knowledge to enable an organization to improve."*[500] Such learning should be both prospective (i.e., using Failure Mode and Effect Analysis; FMEA) and retrospective (i.e., using [critical] incident reporting systems; [C]IRS). In analogy to aviation, Donaldson referred to organizational learning in health care as "passing the orange wire test":

> *"Imagine that a Boeing 757 aircraft engine contained an orange-coloured wire essential to its safe functioning. Imagine that an airline engineer doing a preflight inspection spotted that the wire was frayed in a way that suggested a systematic fault rather than routine wear and tear. Imagine what would happen next. It is likely that most 757 engines in the world would be inspected—probably within days—and the orange wire, if faulty, renewed."*[501]

So, what about health care and the orange wire test? Over the last two decades IRS have generated a lot of momentum in enhancing system safety in health care by organizational learning. The next sections focus on: (1) basic information on prospective (FMEA) and retrospective (IRS) organizational learning; (2) more detailed information about the purpose of IRS, their challenges, and their effectiveness; (3) barriers and facilitators for IRS; (4) characteristics of successful IRS; (5) legal issues of IRS; and (6) the linked idea of independent medical accident investigation boards is discussed based on a recent pioneering safety movement in the United Kingdom.

Failure Mode And Effect Analysis. FMEA has been adapted to health care from engineering systems analysis; it is sometimes used as a tool to analyze adverse events in retrospect. The FMEA approach is to lay out comprehensively the possible failure modes and their effects that could have led to the events and the outcome that occurred. This helps define ways in which the chain of accident evolution could have been prevented or thwarted. A prospective approach to safety can use FMEA techniques to identify safety gaps in advance and implement corrective measures. This can be especially useful for assessing proposed changes to the system—such as introducing a new piece of equipment or a new set of surgical procedures (e.g., starting a liver transplant program where none had existed). Contemplating in advance the ways that things might fail will help determine whether the benefits outweigh the risks organizationally, how best to structure the change, as well as how best to prevent or mitigate problems when they inevitably occur.

(Critical) Incident Reporting System†. The retrospective approach to organizational learning means maximizing the learning to be had from understanding incidents or near misses that have already happened. Even though the terms vary in the literature, based on the *WHO Draft Guidelines for Adverse Event Reporting and Learning Systems*[502] an incident is any deviation from usual medical care that causes harm to a patient or presents a risk of harm. It includes (1) adverse events, where harm is caused to a patient, sometimes also referred to as sentinel events (SE) or critical incidents, as well as (2) near misses. A near miss is a situation that potentially could have turned into a critical incident, but was somehow prevented beforehand. Yet another kind of incident is termed a never event, an incident that results in serious patient harm or death, classified as one that is never the natural result of disease or therapeutic side effect.

Apart from certain mandatory legal reporting and disclosure requirements, (critical) IRSs, sometimes also called patient safety reporting systems (PSRS), are usually voluntary. While original IRS were paper-based, technological progress has allowed the development of mostly electronic or web-based systems. Although IRS adopt various formats, most have the same core operating model: frontline staff, usually those directly involved in an event or actions leading to it, anonymously or confidentially provide detailed information about something that has occurred. In the next step, this report is analyzed—usually free of blame to the reporter—by expert analysts to identify contributing system and human factors, and if applicable, develop strategies for preventing such occurrences. A simplified overview of the core processes of IRS is given in Fig. 6.16. IRS aim to provide systematic organizational learning from local to global levels, recognizing that an incident that occurred in one unit might also be a problem in another unit.

Most HROs have made special efforts to create IRS for incidents of various severity and near misses. Despite several limitations, if IRS is used in a successful way, to quote Charles Vincent,[487] it can serve as a powerful *"window on the system,"* enabling understanding of system problems and safety gaps. In order to function well, IRS need to be easy to use, organizationally integrated and coherent, supported by a culture of safety (see earlier correspondent section), free of sanctions, and linked to feedback about what is being done about the issues reported.

Other methods for organizational learning. Neither FMEA nor IRS alone can optimally enhance patient safety. They are just two of many strategies for soliciting input from frontline staff to creating snapshots of safety issues in the patient care arena. Information from many sources needs to be combined through a systematic assessment of error and harm to obtain the full picture. The U.S. Agency for Healthcare Research and Quality provides a detailed discussion of methods of identifying errors and latent safety problems for organizational learning.[503] Walk rounds by senior leaders and executives also offer a way of collecting data from frontline staff about possible safety hazards.[479]

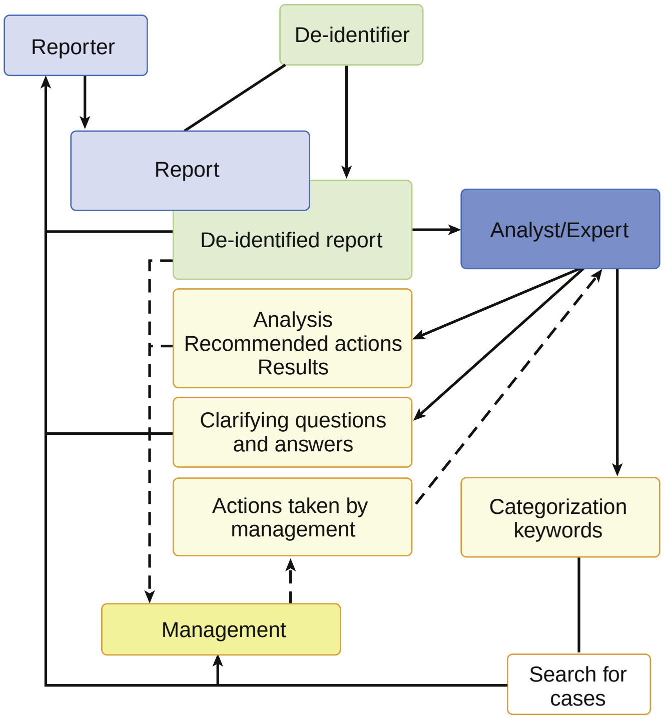

Fig. 6.16 Data handling in a modern incident reporting system with deidentification. The incoming reports are first completely deidentified by a trained deidentifier. Only after this step is the report ready to be analyzed. It is important that the reports are analyzed by a multiprofessional team and that recommendations be fed back to the management of the organization from which the report came. The analysis and feedback should be transparent for all stakeholders.

IRS in health care have drawn their inspiration especially from commercial aviation and the nuclear industry. Unfortunately, the word reporting is a word with a variety of (mostly negative) connotations. In the context of organizational learning it is intended to be regarded as something positive and means communicating safety-relevant information. Anesthesia professionals experience weaknesses and strengths of their work sites during everyday work—valuable information of potential safety gaps that are already out there. By reporting, IRS can help the organization and staff at the rather blunt end of medicine (risk managers, executives, etc.) to extract safety-critical information from frontline staff at first hand, analyze it, and learn from it as an organization. Hence, IRS in a more positive way are often referred to as learning systems, such as the National Reporting and Learning System of the National Patient Safety Agency in the National Health Service (NHS) of the United Kingdom.

Different Operating Modes of Incident Reporting Systems. IRS around the world vary widely in terms of design and operational processes (see Appendix 6.1).[346,502,504-509] IRS can operate at different levels within the health care system: some IRS operate primarily at the local level (i.e., as a tool for local hospital quality and risk management), which may or may not feed into a larger scale; others operate on a larger regional or national scale (i.e., ASA' AIRS). The latter allow (a) a recognition of a pattern of (rare) events that otherwise could not be discerned, and (b) a wider dissemination of lessons learned and solutions created. Both on a local and national level, IRS can be related to a single specialty, or include a broader suite of professional domains. Some IRS accept reports of all kind of events and deviations (i.e., near misses, adverse events, sentinel events, never events, etc.). Others restrict their reports to incidents that match specific narrow criteria.

---

†While reading this section American readers will need to break their ingrained habit of seeing "IRS" as the tax collecting agency of the U.S. federal government (Internal Revenue Service).

The Goals of Incident Reporting Systems. The applicable goals of reporting systems are currently under debate with respect to the way in which data can be used, particularly whether for different combinations of the following: (1) help health care organizations learn and improve, (2) benchmark and compare organizations, (3) hold organizations accountable for safety performance, or (4) help regulators and funders make judgments.[502,510-513] Some of these IRS goals, while compatible in theory, may be mutually exclusive in practice. The emphasis applied to each goal influences system design features, such as whether reporting is mandatory or voluntary, whether reports are confidential or made public, and what kind of incidents are allowed to be reported.

Are IRS effective?. In the United States, all hospitals are required to maintain a confidential event reporting system. In Germany, this has been the case since 2013. Almost two decades ago, Lucian Leape wrote: "If reporting is safe and provides useful information from expert analysis, it can measurably improve safety."[504] Despite their current ubiquity, the actual contribution of these systems to any of their stated goals is uncertain and questions about their effectiveness remain.[514,515]

Challenges and Misunderstandings About Incident Reporting Systems. In a recent paper *"The problem with incident reporting,"* Macrae summarizes a variety of issues surrounding IRS.[512] These include, among many others:

1. Underreporting has been recognized as a major limitation of incident reporting. Of the errors and adverse events that occur in hospital settings, reporting systems capture fewer than 10%.[516] A detailed review of causes of underreporting is described in the section on barriers of reporting. While increasing the absolute number of reports can be useful, their quality is of greatest importance. Charles Vincent stresses that analyzing a small number of incidents thoroughly is probably more valuable than a cursory overview of a large number of incidents.[487]
2. Another widespread misunderstanding of IRS is the idea that the goal of reporting is to provide a numerical metric of harm to patients. In contrary, merely counting incidents is largely uninformative and probably a waste of time.[517] It is sometimes described as a box-checking exercise. Many reports can describe similar events and the relative learning per event shrinks markedly after the first few, whereas some kinds of events are not reported and hence the system may be blind to them. All reporting systems, whether voluntary or not, have serious selection-bias issues—many events are never reported both because it takes effort to do so and because doing so seems to expose the individual and the work setting to risk of reputation loss or other negative consequences.
3. Even at best, IRS provide only partial views on the organization. For a variety of reasons 50% to 80% of the reports are filed by nurses. Physicians file only 1% to 3% of incident reports.[518,519] But many issues involve physician care—up to 94% of the events based on a landmark study.[520] It is likely that to fully understand a system it would be necessary for trained observers (ethnographers) to be embedded in it. Moreover, even if all events were known about in detail the tasks of analyzing and understanding them and finding practical but robust solutions to problems uncovered are far more difficult than merely collecting the information.

BOX 6.12 Important Characteristics of Effective Incident Reporting Systems[11,502,523,527]

- Integration of the incident reporting system into the organization and full support by management
- The absence of negative sanctions for reporters and people involved
- Confidential or anonymous reporting option, with active deidentification (domain expertise required)
- Legal protection and state-of-the-art data security
- Independence of the organizational hierarchy: reports are sent to a trusted subunit outside the hierarchy of the organization or outside the organization (external trust center, e.g., NASA for the ASRS)
- Orientation to a system that enables all stakeholders of patient safety, including physicians, nurses, and technicians, to file reports easily
- Easy and fast reporting
- Training of stakeholders to file valuable reports (e.g., focusing on human factor issues, as well as medical-technical aspects)
- Timely feedback about reception of the report, its analysis, and proposed measures to be taken from it
- Analysis of each report by experts (a multiprofessional team that has a background not only in the medical domain but also in issues of human performance and analysis methods)
- Deep analysis of selected cases by using root cause analyses or failure modes and effect analyses with the aim of improving systems safety in the future
- Timely implementation of improvements to confirm the "reactivity" of the system and to *make a difference*
- Evaluation of improvements and special care to avoid "improvements for the worse" (quick fixes without improving the underlying latent dangers)
- Organizational support of reporting and analysis of cases, as well as the implementation of improvements
- Supports continuous improvement of the positive proactive safety culture in the department (systems perspective!)

ASRS, Aviation Safety Reporting System; *NASA*, National Aeronautics and Space Administration.

Characteristics of Successful Incident Reporting Systems

Reporting Environment. The details of successful IRS are covered in a number of publications,[1,502,505-507,521-527], and summarized in Box 6.12. A culture of safety is a prerequisite for an effective IRS.[502,506] If people fear negative consequences from reports or think that nothing will change, they will not file reports.

Additionally, successful IRS need top management to spread the message of a blame-free and non-punitive objective of IRS and to ensure that the actual activities of the organization comply. Furthermore, health care organizations should be accountable for investigating their own reports.[513]

BARRIERS AND FACILITATORS TO REPORTING. IRS live on the willingness of the staff to report. Common barriers reported by health care professionals include[508]: fear of blame; legal penalties; the perception that incident reporting does not improve patient safety; lack of organizational support; inadequate feedback; no incident follow-up; lack of knowledge about IRS; and lack of understanding about what constitutes an error. Additional aspects found by Firth-Cozens and colleagues[528] were a too-narrow definition of reportable errors and the effort of making the report. Lack of feedback appeared also as the most important barrier in another study of doctors and nurses.[529]

Common facilitators included a non-judgmental environment; the perception that incident reporting improves safety; clarifying what to report and how to do it as well as how the system uses reports; role models (such as managers); legislated protection of reporters; ability to report anonymously.[508] Additional aspects found by Firth-Cozens and colleagues were[528]: improved leadership about safety and errors; learning groups and learning timeouts; cultural change to make clear what is acceptable behavior; action by management to bring about change and to support employees; middle-grade staff on policy committees; support for each other and from management.

WHAT SHOULD BE REPORTED IN INCIDENT REPORTING SYSTEMS AND BY WHOM? In aviation, the cradle of IRS, there are separate reporting systems for incidents (deviations without a negative outcome) versus accidents (with negative outcome). Aviation accidents are investigated by an independent national body (see later section on "Accident Investigation Board"). In contrast to aviation, where the occurrence of an accident is usually quite public and events with negative outcomes are never supposed to happen, in the health care setting every human being will become ill and die someday so that most negative outcomes are inherent to the progression of disease. It is often difficult to determine which outcomes are the result of deviations versus those due to disease itself or inherent side effects.

From the authors' point of view, the invitation to staff to report should be very broad with few limitations on reporting criteria. This way, reporting is simpler for clinicians and staff and a wide net can be cast to identify as many safety-relevant occurrences and system gaps as possible. For this reason many experts believe that for health care event reporting systems, all adverse incidents should be reportable to the system regardless of whether there was a negative outcome. Whereas all health care organization staff should be included for reporting,[506] another interesting approach is to also give patients and relatives the opportunity to report.[502]

Recently Macrae[512] and other experts have argued that the "report it all, catch it all" approach misses an important opportunity to use specific reporting criteria to shape attention to certain events and set priorities on key risks. This becomes increasingly important as an IRS becomes established in an organization and receives a higher volume of reports. In their literature review Stavropoulou and colleagues found evidence that IRS seem more effective if there are explicit criteria for what counts as an incident.[515]

A rather new approach to incident reporting is called learning from excellence,[530] an approach that is in line with the idea of Safety-II (see earlier section). Learning from excellence means that analysis of reports of positive events and excellent performance in which the outcome was good despite challenging clinical circumstances may be as useful as analyzing failures.

There is a risk that certain kinds of IRS can end up being dominated by self-interested claims and complaints.[9] This can happen if staff members are not fully introduced to the goals and operating principles of what to report and why. IRS can also be used as a means for one or more individuals to attempt to exert power over other individuals or groups.

WHAT SHOULD REPORT FORMS LOOK LIKE? Typically, incident forms are partly standardized—to collect basic clinical details—while including the possibility to describe the incident in a free-text field. So-called narrative reports provide the opportunity to capture the rich context and storyline that allow the conditions that contributed to the error to be explored and understood. IRS that rely largely on an array of checkboxes for the reporter to choose relevant causes of the incident have not proven to be as useful.[502,506]

While traditional event reporting systems were paper-based, technological enhancements have allowed the development of web-based systems. On the reporting form, staff should be encouraged to also propose solutions for incidents.[513] Ideally, it should not take long for personnel to complete the form.[529] In the future, IRS reporting might use digital resources such as smartphones, enabling staff to report in near real-time using a device that they are accustomed to.[507]

CONFIDENTIALITY AND ANONYMITY. Usually, reports are submitted by staff members who were directly involved in the events; these professionals may have legitimate concerns about potential effects the reporting could have on their reputation or their employment performance record. Some IRS are entirely anonymous—neither the patient nor the reporting professional can be identified. This grants a high level of protection, although unique aspects of clinical events may make them self-identifying. For organizational learning, anonymous reports carry a major disadvantage: analysts cannot go back and ask for further information to clarify the report (which is often incomplete).

Other IRS, in contrast, are confidential but not anonymous, meaning that the identity of the reporter is known to the system but kept as secret as possible. Ideally there will be strong legal protection from disclosing the reporter's identity (sometimes with exclusions about purposeful professional misconduct or criminal acts). In general, confidential reports should be deidentified as fully as possible, once the full story has been elicited by the analyzing team.[9] Experts suggest that confidential systems should also allow for anonymous reports, as obtaining any report is more important than missing it entirely.[502,506]

Deidentifying reports can tricky. It is not always easy during the deidentification process to balance retaining the key information required to understand the situation versus deleting all possibly identifying data. The combination of facts about a case may be unique and may thus be intrinsically identifiable, even when seemingly all objective identifiers are stripped.[531] Those involved in the deidentification process proper need special training and supervision to ensure that the appropriate balance is achieved.

PATIENT SAFETY ACTION BOX

To learn from errors or incidents and to improve system and patient safety systematically, the primary questions of incident reporting should not address *"who was wrong"* but address *"what was wrong and how/why."* In a next step, incident reporting needs to focus on *"who can do what to prevent such things from happening again."*

Another widespread concern in relation to confidentiality and anonymity is fear of repercussions if reported event is disclosed internally to supervisors or managers. This fear likely influences what is reported, generating a counterproductive filter that prevents important information being passed up the hierarchy.[512] A typical model drawn from aviation is that IRS are operated and managed by an independent safety team that has no influence on personnel decisions and performance records.

Incident Categorization. The next step of the IRS is to categorize it to make it easier to find or link to it internally and to compare data across care providers, possibly using a standardized format.[502,506,513] The most commonly used framework for categorization is the WHO Framework of Critical Incidents (www.who.int/patientsafety/implementation/taxonomy/ICPS-report/en/).

Analysis. A structured and defined mechanism should be in place for analyzing reports.[521] A widely used framework for analysis of reported incidents among many others and variants is the London Protocol by Taylor-Adams and Vincent.[424] Reports should be interpreted by someone who knows the work and knows the context.[517] For health care incident reports to be of most value they should be reviewed by clinicians, perhaps working also with people who can identify the human factors and organizational system issues.[532] The value of multidisciplinary and multiprofessional investigating committees for analyzing incidents is stressed by experts.[522,533] Common findings of an analysis should characterize the problem, draw conclusions, and set out an action plan.[506]

Action. One of the major problems with incident reporting in health care as it stands is that *"we collect too much and do too little."*[512] Structured approaches to developing action plans and change may be helpful.[521] Reporting systems, both local and national, are sometimes overwhelmed by the volume of reports filed. As a consequence, they often fall short in defining recommendations for good and sustainable solutions. In the worst case, so-called quick fixes are produced that themselves trigger new risks. Even well-meaning activities of promoting lessons learned as organizational safety alerts, an updated policy, or new clinical recommendations, will not by themselves promote learning.[512] Learning is a complex social and participative process that involves people actively reflecting on and reorganizing shared knowledge, technologies, and practices.

Apart from an optimal organizational embedding, IRS can be particularly effective when they are successfully integrated and intertwined to other safety measures. For example, linking simulation team-training programs with an IRS allows for mutual input. Using reported incidents in anesthesia as a basis for simulation scenarios makes the training experience and message for the anesthesia professional very relevant to everyday clinical work. Conversely simulations can deepen the understanding of how and why things happened the way they did, and the experience of simulations can trigger participating clinicians to be more interested in reporting to the IRS in the future.

Feedback. Timely feedback should be given to the reporter, confirming that the report was received and is being processed so that they do not feel that their report was just tossed aside.[497,504] In the course, the reporter should be individually kept informed of next steps and actions taken. Failure to receive feedback after reporting an event and the perception that incident reporting neither brings change nor improves patient safety frustrates reporters. Summaries of reported events (deidentified) should be disseminated in a timely fashion to staff.[521] A variety of complementary feedback modes have been described.[507,534] Researchers have described a safety action feedback loop. This feedback loop unfortunately receives inadequate attention in many organizations,[512,522] leading to the perception of IRS as black holes (reports go in but nothing useful ever seems to come out). Clinical managers should seek to use action feedback information to motivate their staff.[535]

In the past 15 years, research about IRS have focused primarily on setting the stage for technical infrastructure, report collection forms, and categorization and analysis tools. Although those foundations are important, *"over the next 15 years we must refocus our efforts and develop more sophisticated infrastructures for investigation, learning and sharing, …"* (p. 74).[512] Leistikow and colleagues controversially argue that "the journey, not the arrival matters," meaning to focus more on how hospitals learn from incidents and less on what hospitals learn.[511]

LEGAL ISSUES OF REPORTING SYSTEMS. Especially in jurisdictions for which medical liability litigation is common, certain legal issues affect reporting systems. For some kinds of events in some settings, legal requirements to report the event to a governmental body may be in place. This is true in the United States for certain kinds of adverse drug events or for certain failures of medical devices. Moreover, some U.S. states have started mandatory reporting programs about certain never events. In general, voluntary IRS operate completely separate from these governmental types of reporting systems.

In the United States there are various aspects of law in individual states and at the federal level that can provide statutory protection (shield) from discovery (in litigation) of certain kinds of reports to certain organizations. The U.S. Congress passed the Patient Safety and Quality Improvement Act of 2005 (Public Law 109-41)—implemented in 2009—providing for the Department of Health and Human Services to certify patient safety organizations (PSOs) to collect confidential reports about events and to analyze the information. The act provides strong legal protection (privilege) from any compelled release of the information, as in the process of discovery in a lawsuit. Separate privilege from discovery may be granted in states that provide it for internal reporting systems within hospitals that are quality improvement activities, but state laws vary widely on this matter. In addition, the quality improvement protections are often challenged during litigation, and whether the privilege will be applied depends on the ruling of a judge in each individual case. Reporting systems in other countries have used different strategies. For example, in Germany, national IRS have constituted themselves as a press office (informing the anesthesia public domain as journalists would); this then brings them under the protection of the free press act and rights, and makes it almost impossible to use its data in litigation.

The Anesthesia Incident Reporting System in the United States. In 2011 the Anesthesia Quality Institute, affiliated with the ASA, initiated the Anesthesia IRS (AIRS) to collect reports of critical events in anesthesia. Incidents can be reported by secure web-based data collection, either confidentially or anonymously. Confidential reporting allows the AIRS analyst to contact the individual for clarification or follow-up. Legal protection is provided by U.S. federal legislation described above. The law also imposes strict guidelines on how confidentiality of the work must be preserved. The AIRS publishes regularly on their Homepage as well a monthly column in the ASA Newsletter, in which it describes—in deidentified form—an interesting case report and its analysis by the AIRS Committee (Lit: https://www.aqihq.org/casereportsandcommittee.aspx). As of October 2018, AIRS has published a case analysis every month since October 2011. AIRS has instituted 4 specialty modules to collect data about events in certain categories of special interest: (1) cases that involved a respiratory depression event; (2) cases that involved a lack of necessary medications (drug shortage); (3) cases that fall under the OB/GYN procedural service type or took place in an institution's OB ward; (4) cases for patients under the age of 18 (pediatrics).

Should Health Care have an Independent Organization for Accident Investigation? As noted, serious incidents and transportation accidents in aviation and other industries are investigated by an entirely independent, interdisciplinary governmental safety investigator. For example the National Transportation Safety Board (NTSB; www.ntsb.gov) in the United States; similar agencies exist in most countries. These generally provide for rapid—usually in well under 24 hours—deployment of expert accident investigators to the scene of accidents with extensive laboratory and analytical facilities and expertise headquarters.

For several decades, suggestions have been made to establish an NTSB-like body to investigate accidents in health care. Especially in the past few years, new calls have been made to establish such an organization.[536] Until 2017, the complexities and pitfalls of such an investigation, including the fact that adverse outcomes are several orders of magnitude more common in health care than in commercial aviation, have obstructed any progress toward creating such a program. In April 2017, the United Kingdom began to operate the first independent investigation body, the Healthcare Safety Investigation Branch (HSIB; www.hsib.org.uk). Even though funded by the Department of Health and hosted by the NHS Improvement, the multidisciplinary team of experienced safety investigators operates independently. Future developments will show what benefit and usage will derive from this activity.

The debate about the feasibility and advisability of such high-level investigating organizations in different jurisdictions will probably continue for a long time. We believe professional investigation of safety critical events and harm, with rapid deployment and expert analysis, will lead to new insights and the implementation of practical, robust, and effective solutions.

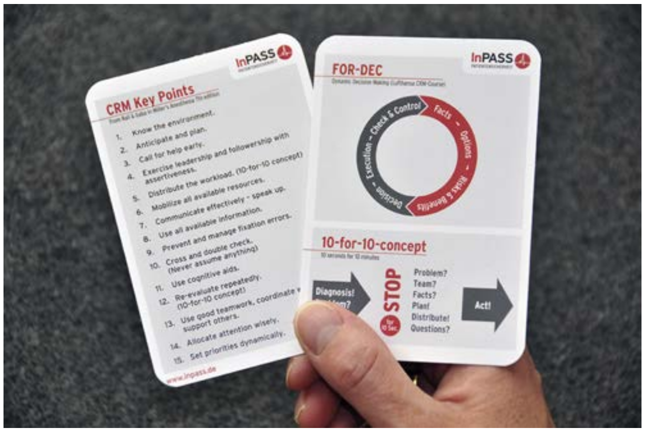
Continuous Training including simulation

Small groups of individuals work together throughout perioperative care. Anesthesia professionals, surgeons, nurses, and other health professionals must coordinate their activities in order to make safe and efficient patient care the priority. Whereas teams in the classical sense work together over a longer period of time, the configuration of teams in the dynamic and frequently changing setting of the OR or ICU environment contains particular challenges of so-called action teams (see earlier section on "Teamwork"). Members of action teams are rarely trained together, and to-date, few are trained at all specifically in how to manage challenging situations providing safe care, for example, by applying the CRM concept (see earlier section on "Crisis Resource Management"). Moreover, they come from distinctly different disciplines and diverse educational backgrounds to the extent that they are often described as being in silos or tribes. The varied nature of the work and the necessity for cooperation among those who perform it make team training an ideal tool in the drive to improve patient safety and reduce medical errors.

How the CRM concept can be learned, trained, and implemented best is explained more in detail in the upcoming section. More detailed information on the conduct and modalities of modern simulation team training for health care professionals can be found in Chapter 7.

How Can Crisis Resource Management-related Skills be Learned, Trained, and Sustained? Despite the growing evidence, systematic interventions to improve patient and system safety have only partially penetrated medical thinking and teaching. CRM-oriented training and behavior should be one component of a comprehensive approach to addressing human factors issues in anesthesia safety, but few if any institutions have deployed such integrated approaches. There have been several reviews on the variety of MTTs, the latest published by Weaver and colleagues in 2014.[409] The targeted teamwork competencies of the programs they discuss are similar, but the curricula differ widely: in content, duration, participation frequency of clinicians and staff, delivery strategies (didactic, seminar, simulation/debriefing), maintenance strategies, and evaluation effort. One major question seems to be the degree to which simulation adds to simple classroom activities.

Two Different Approaches of Team Training: Simulation-Based or Classroom-Based? The oldest medical CRM curriculum, namely the ACRM curriculum, relies heavily on high-fidelity simulation-based training, introducing the CRM principles to the participants and then highlighting CRM aspects of medical care in the post-scenario debriefings. A pocket card of the 15 CRM key points is shown in Fig. 6.17.



InPASS
CRM Key Points
1. Know the environment.
2. Anticipate and plan.
3. Call for help early.
4. Exercise leadership and followership with assertiveness.
5. Distribute the workload. (10-for-10 concept)
6. Mobilize all available resources.
7. Communicate effectively - speak up.
8. Use all available information.
9. Prevent and manage fixation errors.
10. Cross and double check. (Never assume anything)
11. Use cognitive aids.
12. Re-evaluate repeatedly. (10-for-10 concept)
13. Use good teamwork, coordinate
support others.
14. Allocate attention wisely.
15. Set priorities dynamically.

Fig. 6.17 Crisis resource management (CRM) pocket cards. One side of the cards shows the 15 CRM key principles by Rall and Gaba. The other side of the card shows two graphics. One shows a tool for formalizing decision-making and avoiding fixation errors called "FOR-DEC," which is derived from aviation. Another shows the "10-seconds-for-10-minutes" concept, a reminder to take the necessary time to organize into a team, whenever appropriate. The cards are handy and pocket sized, and can be carried around during work as a reminder or can be distributed in the department as reminder, an interest-gaining or a multiplication tool. During the CRM courses or simulation training sessions of the authors, CRM pocket cards are given to each participant. (Photograph by M. Rall.)

Much simpler than simulation-based training is purely seminar-based training about human factors, CRM principles, teamwork, and team communication. Several team training programs, including MedTeams, MTM, and DOM, rely on classroom-based approaches only and use didactic lectures, group exercises and role plays, discussion, and analysis of trigger videos.

The different concepts of these training programs, probably as well as the cost and manpower of high-fidelity simulation and the small number of participants per simulation session, raised the question whether simulation-based CRM training is needed compared to classroom-based training and whether they are equally effective. Only a few studies have investigated the effectiveness of classroom-based team trainings versus simulator-based programs.[537] Weaver's summary of review findings reported similar positive effects on learner reactions, knowledge or skills, and clinical practices, as well as patient outcomes.[409] Riley et al. compared perinatal work areas in three different hospitals; one participated in a didactic team-training program, one participated in an in situ simulation program, and one served as a control.[538] Results indicated that significantly greater reductions in patient harm were achieved by the group that participated in the in situ simulation program compared with both the didactic and control groups (37% reduction vs. 1% reduction vs. 43% increase in harm, respectively). The lessons learned from the implementation of the Veteran Affairs (VA) MTT program introduced earlier also suggest that simulation is a crucial part of CRM-based team training interventions.[414]

Drawing parallels to the translated CRM training curriculum in aviation, the classroom-based approach correlates with what the Federal Aviation Agency (FAA) calls phase I (awareness), whereas the simulation-based approach correlates with phase II (skills practice and feedback), which is followed by phase III for maintenance (recurrence training). This is in accordance with the comprehensive approach to teamwork training of Salas and colleagues.

This didactic approach suggests three elements needed for adult education: (1) convey knowledge about teamwork, (2) develop skills of teamwork, and (3) enhance attitudes concerning teamwork.[539,540] Gaba wrote in a point-counterpoint discussion about the question "What does simulation add to teamwork training"[541] the following, proposing the benefit of simulation-based CRM training:

> *"Didactic training may address knowledge and can influence attitudes, but to fully develop skills and alter attitudes, experiential training [like simulation-based training] is likely to be the most effective. Thus, given the complexity of the topic, it is likely that multiple approaches will be necessary to maximize learning and transfer to real patient care."*

Pratt and Sachs challenge this view, arguing that the rather complex and costly simulation approach is replaceable with classroom-based teaching and intensive coaching of clinicians during and after real patient care activities.[542] A rather new approach is the concept of teaching CRM-related topics with a screen-based interactive virtual simulation featuring typical clinical situations.[543,544] Even though virtual simulations permit flexible, cost-efficient, and asynchronous learning, the role and the effectiveness of such virtual activities away from a physical team intervention have to be further evaluated.

Gaba continued in the aforementioned discussion:

> *"Moreover, it is also likely that no single course or exercise can change such complex behaviors permanently—only long-term repetitive training and practice, combined with solid reinforcement of the principles and skills in the actual work environment, has any chance of developing new and optimal teamwork patterns that become deeply ingrained in the work culture."*[541]

It seems reasonable to combine best practices from classroom-based and simulation-based training for an optimal CRM team-training experience. More and more CRM-related organizational or departmental interventions now do so, following the classical phases I (awareness) and II (practical skills and feedback) of the aviation CRM curriculum: that is, ACRM curriculum, TeamSTEPPS, VA CTT, and several CRM implementation studies. Primarily, staff participates in seminar-based CRM interventions in order to learn about the concepts and to create awareness. Simulation-based training is then used after or during the classroom introduction to apply the theoretical knowledge during practical medical case scenarios and to get feedback or to refresh knowledge in order to reach a sustainable base over time. More details on the simulation-based approach are provided in Chapter 7. More details on different ways of teaching ACRM—both simulation- and classroom-based—can be found in the second edition of the book *Crisis Management in Anesthesiology*.[14]

We believe that practicing the reliable execution of CRM skills in routine and emergency situations requires, among other things, exposure to challenging clinical situations in realistic simulation scenarios, followed by detailed group debriefings led by qualified instructors to analyze what transpired. As discussed in Chapter 7, Such CRM-oriented simulation training may be available in dedicated simulation centers or as in situ simulation training in actual work environments. Many simulation centers offer mobile simulation training whereby a simulation team can bring the simulator and simulation equipment to another facility to train the staff in institutions that do not have a simulator or the relevant instructors. Another way is to prepare a few of a site's own clinicians to conduct CRM-based simulation team trainings by sending them to one of the instructor courses for CRM-based simulation team training. Although there are many such courses, the three best known sites of instructor training in the United States are at the Center for Medical Simulation in Boston, the Center for Immersive and Simulation-based Learning at Stanford School of Medicine, and WISER at University of Pittsburgh. In Europe, among others there is the InPASS InFacT instructor course (by Rall), the instructor courses run by DIMS (by Dieckmann), and the EuSiM instructor course.

When choosing a train-the-trainer course, it is important to understand that simulation is a technique, not a technology. It takes many forms: from nontechnological modalities (e.g. verbal simulation, role-playing) to simple skills training models to computerized full-body mannequins; from training students to training professional teams, from rather simple mega-code training scenarios to complex emergency scenario design. Each training form requires a different amount of manpower, logistics, and costs. But crucial under all circumstances is the special skills of the simulation instructors in course and scenario preparation, scenario execution, and debriefing (see Chapter 7). In order to use simulation successfully, the simulation instructors need to be specially qualified in CRM-based training (see Chapter x), the learning objectives of the simulation training need to be set (see Chapter x), and the needs of learners at each stage of education must be targeted (see Chapter x). Furthermore, for simulation to be effective it needs to be integrated into the strategic concept of an organization in a way that promotes transfer of the ideas and skills learned to clinical practice.

Reinforcement and Sustainability of Team Training Effects. Sustainability of team training effects over time is a common question among both improvement scientists and practitioners. Many early evaluations of team training limited follow-up evaluations to 6 months post-training or less.[409] Positive responses after a simulation-based CRM intervention have been found to last for up to 6 months after training.[347] Patterson found gains in teamwork knowledge sustained at follow-up conducted 8 to 10 months post-training.[242] In studies examining the implementation of the VA's team training program, results indicated both significant improvements in perceptions of teamwork climate up to 11 months following implementation[545] and statistically significant reductions in surgical mortality 1 year post training.[42] Those numbers mimic the findings of Armour et al. who indicated a decay in gains 1 year post training.[397]

While a great deal of work has been dedicated to examining optimal refresher training intervals for clinical procedural skills (e.g., resuscitation or intubation skills), relatively minimal work has been done to understand optimal refresher intervals for teamwork competencies. Moffatt and colleagues offered a recurrent training two years after the initial training.[41] The VA CTT program conducts mandatory recurrent training one year after the initial training session, viewing this approach *"critical to re-enforcing key CRM concepts in the program."*[546] Nothing is stated in the program about further training frequency after one year. Based on the literature findings and also drawing parallels to the CRM curriculum in aviation (phase III: recurrence training), a refresher interval of one year for CRM team trainings would seem rational, but we do not know of any institutions that do full-day sessions for experienced clinicians this frequently.

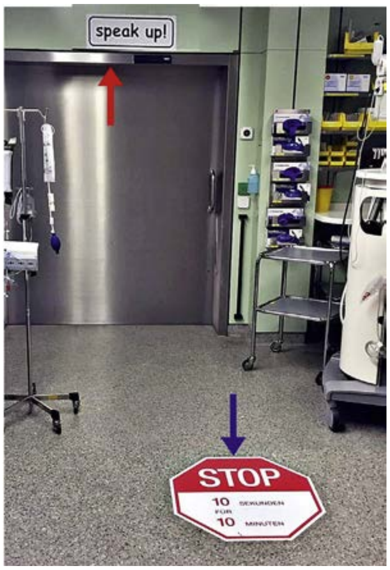

Fig. 6.18 Example of the organizational integration of "Speaking up" and "STOP! 10-seconds-for-10-minutes." The photo shows a laminated sign with the words "Speak up" above the trauma room door (red arrow) and a laminated sign with the words "Stop! 10-seconds-for-10-minutes" on the floor (blue arrow) at the University Hospital of Zurich, Switzerland. The signs are placed as a reminders for safety tools for clinical teams and at the same time show the organizational effort and support for patient safety issues. (Photos published with permission of University Hospital Zurich [USZ], Center for Simulation [Chair: M. Kolbe]).

It is important not think about simulation as a one-shot thing once or every now and then, but rather about a career-long set of activities. These might sometimes take place in a dedicated simulation center or a hospital simulation area and sometimes in situ, directly where patients are treated and cared for.[547] If simulation activities are combined this way it stands to reason that there will be an accumulation of change in individual and team skills, knowledge, attitudes, and behaviors as well as in systems probing and systems change.

Organizational Aspects of the Implementation and Sustainability of Team Training. As with nearly all patient safety principles, application of CRM key points to patient care must be supported by top leadership and reinforced in the actual work environment (Fig. 6.18). It is of less use to study these principles (or even practice them in simulations) only to find that the pressures and culture of the real OR make them impossible to implement. Fully integrating the concepts underlying the CRM key points into the structures and processes of clinical practice has proven to be a significant challenge. The Joint Commission Journal on Quality and Patient Safety outlined several critical factors for developing successful team training in 2009.[539] In brief, those are:

- Align team training objectives and safety aims with organizational goals.
- Provide organizational support for the team training initiative.
- Get frontline care leaders on board.
- Prepare the environment and trainees for team training.
- Determine required resources and time commitment and ensure their availability.
- Facilitate application of trained teamwork skills on the job.
- Measure the effectiveness of the team training program.

Box 6.13 shows characteristics of the implementation of team training interventions that have proved to be successful characteristics.

Continuous Optimization of Safety-Relevant Structures and Processes

HROs try to continually alter the way that they work to improve safety—the structure of their organization, its work units (sometimes described as microsystems), and teams, as well as the usual processes and protocols of care. Sometimes, but not always, these changes can also improve efficiency as well as safety. Since individual workarounds succeed only one patient at a time, addressing the flow of everyday work, and the preparations for anomalies or crises, will be critical to making lasting improvement.

In order to optimize structures and processes continuously in regard to patient safety, it is important to maintain a culture of safety (see above) so that frontline staff are willing and enabled to contribute actively. Furthermore, when talking about the optimization of structures and processes in regard to safety, it is important to define and generate structured ways to transfer safety-critical information and topics, for example from IRS (see earlier section) and team training events (see earlier section) to those who are in charge of structural changes.

Surely, there are many different ways to optimize structures and processes. Starting points, for example, could be the aforementioned use of walkrounds[479] and closing performance gaps by using debriefing as formative assessment[548] after routine and non-routine events.

In many places, the optimization of structures and processes lies in the hand of quality and risk managers. However, we have observed gaps between what is optimized by those working at the blunt end and what is acknowledged and played out by personnel at the sharp end.[549] In order to master this challenge, from the authors' point of view and based on the view of other experts, it is important to:

- focus on the four main elements of safety culture, organizational learning (i.e., IRS), team training, and optimization of structures and processes in a very balanced manner
- develop and optimize structures and processes together and with close involvement of clinical teams (participatory development and user-centered iterative design)

BOX 6.13 Characteristics of Successful Team Training

Studies[5,41,42,414,546,562] that evaluated the positive impact of the implementation of a CRM team-training program and that were successful, show the following, or part of the following, characteristics for the implementation and training process:

Preparation and Implementation

- Assess measures of collaboration and standardization (i.e., 2 months), followed by planning the implementation (i.e., 1 month) based on individual organizational aspects
- Appointment of a “steering committee” consisting of hospital medical and nursing leadership
- Create leadership support and engage departmental teams for planning and preparation

Initiation

- Administrative Training: Intensive training of the leadership group, for example, chief executive officer, chief financial officer, dean, chief medical officer, chief quality officer, department chairs, division heads (i.e., 2 days)
- Administrative Training: Training of executive and senior leadership, board members, and perioperative departmental leadership attending the same CRM training that all perioperative physicians and staff attend.
- Staff Training: Mandatory CRM training session for all physicians and nurses participating in the intervention. Some programs first started on a voluntary basis (“pilot”)
- Interactive training and training in interprofessional teams
- Small groups (i.e., 15 participants/group) and sufficient exposition time for the lectures and interactive training sessions (i.e., 2 day à 9 h[5]; 1 day[42]; 4 h[41])
- Introduction of CRM with en bloc-training (all department staff participates in the training in a short time span, i.e., within 2 or 3 months)
- Team training provided by CRM qualified and experienced instructors; peer-to-peer communication is helpful
- Sufficient Trainer: Participant ratio is 2:15 for moderated interactive group work
- Training is a mixture of lectures and interactive elements (i.e., workshops, discussions, etc.)
- The potential for disturbance is as low as possible (i.e., no duty calls, no pagers, etc.) Eventually ORs must be closed for the training sessions
- Training tailored to organizational/departmental needs

Maintenance

- Creation of a CRM work group consisting of frontline clinicians, giving input to CRM every now and then (posts, bulletin notes, CRM as standard item during morning rounds and staff meetings, etc.), translating CRM into the organizational needs (professional ownership), and organizing several CRM activities (i.e., “week of CRM,” refresher lectures, CRM “awards,” etc.)
- CRM as part of the yearly individual evaluations
- Nomination of local “champions”
- Coaching and monitoring of unit-based performance outcomes (i.e., over 12 months) or “follow-up support” is provided
- Mandatory team training of all new staff members
- Mandatory “practical training” (i.e., CRM-based simulation team training)
- Mandatory “recurrence training” (after 1 year of initial training, not mandatory after 2 years of initial training)
- Steering committee continues to meet monthly to monitor progress
- Initiation of a “train-the-trainer program” to promote hospital’s own CRM facilitators and internalize CRM training and implementation

- introduce and implement new processes and structures systematically, taking whatever time is needed to do this effectively rather than just rolling it out haphazardly. This likely needs change control to determine first how and where the new processes will involve and influence other activities, information that will best come from discussions with clinical personnel and their managers.
- adjust processes and structures in regard to findings from human factors engineering; sometimes it is the work environment or equipment that need to be changed and adapted to the realities of human performance rather than the other way around.

As it is rarely possible to implement or strengthen the four main elements of an HRO all at the same time; it is important to proceed step by step and balance the focus between the elements. Establishing a culture of safety is one of the most important goals as this element is incredibly intertwined with the success of the other elements. Nevertheless, a strong focus on human performance and patient safety within organizations lies in the optimization of structures and processes and IRS. At the same time, organizations should continually train their medical personnel about issues of human performance and patient safety, because there are three related challenges:

- **What do frontline personnel do until all structures and processes are optimized?** The development of strong and safe structures and processes cannot be achieved overnight. Many processes and structures need optimization. While this is going on clinical teams continue to treat patients day after day. They need to hone their skills even while working with outmoded structures and procedures.
- **Even when improved, no system and no process is perfect.** Even optimized processes and structures hold pitfalls; clinical teams will always need to compensate for them and for safety gaps. Only if the individuals and teams have learned and trained together in how to do so can they can operate safely—essentially *"people create safety"* (p. 267).[9]
- **At the very end of any structure or process there always stands a human being.** Regardless of whether the structures and processes are optimized, for the foreseeable future a human professional is at the sharp end of patient care, executing those processes and procedures, and consciously or inadvertently altering or bypassing them. Therefore they need to know and be able to use all relevant safety strategies. These professionals are indeed the last barriers against catastrophe and hence each should individually also exemplify the ideals of HROs, promoting resilience and flexibility at the same time (see earlier sections).

The behavior, commitment, and engagement of frontline staff itself is the crucial key to translate organizational intentions into practice. Our experience is that CRM-based simulation team training (clinical action and clinical relevance) with focus on human performance elements and patient safety can be a good starting point to gain the understanding and buy-in of clinical personnel to organizational changes.

The Bigger Picture: Patient Safety Efforts on the U.S. National and International Level

PATIENT SAFETY MILESTONES AND MOVEMENTS

The field of anesthesiology can rightly be proud of introducing the idea that patient safety is not just a byproduct of clinicians doing a good job, but rather is something to be studied, sought, and fought for as a matter in its own right. This was in large measure achieved by Jeffrey B. Cooper (at Massachusetts General Hospital) and Ellison C. (Jeep) Pierce, Jr., (when president of the ASA), who created a Committee on Patient Safety. Jeff, Jeep, and a few other like-minded innovators created the Anesthesia Patient Safety Foundation. These developments are acknowledged to be the founding milestones of the patient safety endeavor, and the inspiration for further development of similar organizations for all aspects of health care across the world.

In part through the efforts of such PSOs the medical community became more open to taking a harder look at medical human performance, error, and negative outcomes. Since the 1990s, many landmark publications and activities have addressed patient safety and the organizational aspects of reducing errors.[9,11,174,434,550-552]

Although many scholars within and outside of anesthesiology had been addressing these issues for some years, the report of the IOM in 1999, *To Err Is Human,*[174] was a highly publicized awakening in the United States about the problems of patient safety. Summarizing the primary literature, the report stated that *"tens of thousands die each year from errors in their care and hundreds of thousands suffer or barely escape from nonfatal injuries that a truly high-quality care system would largely prevent."* The subsequent report of the IOM Committee on Quality of Health Care in America in 2001, entitled *Crossing the Quality Chasm: A New Health System for the 21st Century,*[434] took a systematic approach to improvement of the entire health care system. It stated that *"between the health care we have and the care we could have, lies not just a gap, but a chasm"* because the health care system today harms too frequently yet routinely fails to deliver its potential benefits. The report concluded: *"The current care system cannot do the job. Trying harder will not work. Changing the systems of care will."*

Various other efforts have taken place, including the *"100,000 Lives Campaign"* (2004) by the IHI; the WHO patient safety program (2004); the patient safety enhancing *TeamSTEPPS* program (2005 and revised 2013); the *Patient Safety and Quality Improvement Act* establishing a voluntary IRS and providing privilege and confidentiality protections for reported patient safety information; the introduction of the *WHO Surgical Safety Checklist* (2008); and the *WHO Patient Safety Curriculum* (2011).

Fifteen years after the IOM report "*To Err is Human,*" the National Patient Safety Foundation (NPSF) convened an expert panel in 2015 to assess the state of the patient safety field and set the stage for the next 15 years of work. Among the recommendations[471] are: establishment of a total systems approach and a culture of safety, and calls for action by government, regulators, health professionals, and others to place higher priority on patient safety science and implementation. The Helsinki Declaration on Patient Safety in Anesthesiology[553] in 2010 from the European Board of Anesthesiology (EBA) and the European Society of Anesthesiology (ESA) emphasized the role of anesthesiology in promoting safe perioperative care in Europe.[371]

Institutions Engaging in Patient Safety

Several governmental and non-governmental patient safety institutions have emerged over the past two decades, including the National Patient Safety Foundation (NPSF), the Agency for Healthcare Research and Quality (AHRQ), and the IHI in the United States; the National Patient Safety Agency (NPSA) in England; the Canadian Patient Safety Institute (CPSI); and many more.

Raising the Awareness for Patient Safety

In 2003 the NPSF initiated a patient safety awareness week that takes place yearly, highlighting different patient safety topics. Two years later, in 2005, the WHO launched a yearly Patient Safety Day for increasing the awareness of patient safety.

Certified Education in Patient Safety for Health Care Professionals

The NPSF created the Certified Professional in Patient Safety (CPPS) credential to establish core standards and benchmarking for the field and set an expected proficiency level for those seeking to become professionally certified in patient safety. By 2018, more than 2000 professionals have achieved the CPPS credential. They represent physicians, nurses, pharmacists, patient safety professionals, quality and risk management professionals, health care executives, nonclinical health care professionals, and others with the requisite background throughout the United States and nine other countries. The content of certification covers knowledge in the following five key elements: safety culture, leadership, patient safety risks and solutions, measuring and improving performance, and systems thinking and design/human factors. The VA National Center for Patient Safety, in cooperation with the VA Office of Academic Affiliations, offers one-year fellowships in patient safety to provide in-depth education in patient safety practice and leadership.

National and International Evaluation of the Benefits of Patient Safety Programs

Over the last years the focus of patient safety initiatives has been put more and more on the question of economy and efficiency. Two major reports demonstrate the cost benefits of patient safety programs: (1) The report provided by the AHRQ in 2016 displays interim data on national efforts from 2010 to 2015 to improve safety in health care.[44,554] The report showed that hospital acquired conditions (HACs) have been declining since 2010 with many fewer deaths and substantial dollar savings. (2) The report launched by the international Organization for Economic Cooperation and Development (OECD) on the economics of patient safety in 2017. [472] The report estimated patient harm being the 14th leading cause of global disease burden and resulting in a considerable cost to patients, health care systems, and societies. Key messages emphasized the important role of leadership and the building of a positive safety culture. Similar economic success, but on the organizational level, was demonstrated in 2017 by Moffatt-Bruce and colleagues at an academic medical center.[41]

Patients for Patient Safety

Furthermore, more and more attention is drawn to the support of patient engagement as a vital contributing component of safe care. The WHO launched the safety program Patients for Patient Safety and provides several toolkits for patients. Several programs in Canada, Australia, and the United States, for example, have been launched, following the idea of patients being the extra sets of eyes and ears that should be integrated into the safety processes.[555-557] Patients are more likely to participate and speak up if they feel authorized and supported to do so by health care workers. As a consequence, the successful setup of patient empowerment strategies requires the understanding of benefit by health care workers to buy in and then requires their full support.

Conclusion and Outlook

Avoiding errors and harm to patients is crucial for every anesthesiologist. For the safety of the patients, but also for the psychological well-being of us as professionals, as professionals commonly suffer from patient harm as a second victim. Clinical knowledge and skills are not sufficient to harm any patient during care. This chapter has summarized, in regard to anesthesiology, how human performance issues matter. As can be gleaned from this chapter, there are many challenges to individual, team, and system performance that can degrade the ability to achieve safe and high-quality care. Knowing and teaching about these is the first of many steps to address them. Recurrent training and practice, with simulation as an important component, organizational learning after both successes and failures, and continuous fostering of a culture of safety and improvement will be needed. As Sir Liam Donaldson stated in 2004 to the Alliance for Patient Safety Conference in Washington: *"To err is human, to cover up is unforgivable, and to fail to learn is inexcusable."*

Anesthesia professionals can and should collaborate with their partners in surgery, nursing, and beyond; however, ultimately anesthesia professionals need to take responsibility for ensuring that we as individuals, the teams we work in, and our workplaces, are ever ready to provide the very best care.

Patient safety has generated a lot of momentum over the last 30 years. Many achievements have been made, although a lot of issues remain to be addressed satisfactorily in part because at their root are fundamental aspects of the way that health care is organized. Even countries that are pioneers in patient safety still struggle. In the developing world and low-resource settings, even basic aspects of patient safety still need to be addressed. Patient safety is a never ending battle, regardless of resources, and as Charles Vincent put it: "Safety in health care is a moving target."[558]

Many patient safety pioneers in medicine, including us (the authors), thought that many of the issues introduced in this chapter would be roughly a decade-long proposition. Now, with many of us being in our fourth decade of the patient safety journey, we know that the road goes ever on…

… and we all just have to keep on trucking.

Acknowledgment

The editors, publisher, and Drs. Marcus Rall, David M. Gaba, and Peter Dieckmann would like to thank Dr. Steven K. Howard for his contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Patient Simulation

STEPHANIE MARIA OBERFRANK, MARCUS RALL, PETER DIECKMANN,
MICHAELA KOLBE, and DAVID M. GABA

KEY POINTS

- Led by the discipline of anesthesiology, simulators and the use of simulation have become integral parts of many health care domains for various uses including training of novices, advanced residents, and experienced professionals; research about and with simulation; system probing; and performance assessment. Patient simulation can be part of an organization's patient safety strategy and supports building a culture of safety (see Chapter 6).
- A wide variety of simulators are now available. The pace of technical development and applications is fast. Nevertheless, technology alone does not teach. The use of simulators needs to be consistent with the target population and the learning objectives. Different simulators may be best suited for different purposes; for some scenarios and teaching goals a standardized patient (actor) may be more effective.
- The most widely used simulators in health care are computer screen-based simulators (microsimulators), and part-task trainers mocking parts of a human body or mannequin-based simulators most often used for resuscitation training and complex team training. Complex simulation team training with mannequin-based simulators are often referred to as "high-fidelity" or "full scale" patient simulation training.
- The development of mobile and less expensive simulator models allowed for substantial expansion of simulation training to areas and locales where this training could not previously be afforded or conducted (so-called in situ simulation training).
- When used for education and training, the simulator device alone does not teach. It is merely a tool to accomplish learning objectives that are difficult to achieve during real patient care. The design of programs, curricula, scenarios, and debriefings, as well as the ability of simulation instructors to create appropriate learning opportunities are the crucial factors that determine whether the simulation tool is effective in achieving the relevant goals.
- The greatest obstacles to providing effective and relevant (high-fidelity) patient simulation training are (1) obtaining access to the learner population for the requisite time, and (2) providing appropriately trained and skilled simulation instructors to prepare, conduct, debrief, and evaluate the simulation sessions.
- The most important component of high-fidelity patient simulation training is the self-reflective (often video-assisted) debriefing session after the clinical scenario. The quality of debriefing strongly depends on the training, skills, and experience of the instructors. Thus, special training for developing patient simulation instructors is needed that goes beyond the instructor qualifications for ordinary clinical teaching. Most methods of debriefing emphasize open-ended questions and inquiry to trigger self-reflection and insightful analysis, leading to deep learning by the learner group.
- Simulation scenarios need clear learning objectives for both clinical and nonclinical skills (human factors, see Chapter 6). Scenarios need to take into account the target population, learning goals, relevance, and in-scenario guidance. Maximum realism is not always needed. For high-fidelity patient simulation team training, the *anesthesia crisis resource management* course model (ACRM, often referred to as CRM, developed by one of the authors [David Gaba], see Chapter 6) is a popular approach worldwide for human factor–based simulation training in anesthesiology and health care. The 15 CRM key points help individuals and teams to be aware of human factor–related pitfalls, apply different safety strategies, and enhance human performance and patient safety.
- In terms of research, simulation has proven valuable to study relevant simulation aspects such as debriefing methods, scenario design and conduct, and program development. It also was found to be valuable to study human performance during anesthesia, including human factors and failure modes in care.
- In regard to system probing, simulation can be used successfully for the testing of an organization's structures and processes, such as the early detection of system failure modes and the preparedness for major events, the development of new treatment concepts (e.g., checklist design and use, telemedicine), and the support of bioengineering system development (e.g., device beta-testing, educating the manufacturers' workforce).
- With a view to assessment and evaluation of performance, a variety of assessment tools and behavioral markers have evolved that offer a new window on performance. Nevertheless, when simulation is used to assess and evaluate human performance, the unique constraints of simulation (which is never like the real thing) need to be taken into consideration.

What This Chapter Is About: An Overview

> *"Simulation training in all its forms will be a vital part of building a safer health care system" [p. 55].*[1]
>
> SIR LIAM DONALDSON, CMO ANNUAL REPORT (2008)

In concert with other modalities, simulation can improve patient safety by informing personnel about best practices, guiding established clinical practice, and strengthening human performance. Unfortunately, simulation in health care is still not used as widely and systematically as needed, compared to its use in other high-risk/high-reliability industries. From the authors' point of view, anesthesia professionals, anesthesia departments, and health care organizations need to strive to embrace the use of simulation for the many purposes mentioned in this chapter. Simulation, in combination with human factors training (CRM, see Chapter 6), has the potential to substantially improve the quality and safety of health care.

Anesthesiology has pioneered the field of simulation in health care. The rather new, mannequin-based patient simulators have been in regular use in anesthesiology since the early 1990s. Over the last two decades, there have been many technologic advances in simulation and a wide variety of applications of simulation in anesthesiology have been developed in the domains of education and training, research, system and equipment probing, and assessment. Considerable collective experience has already been achieved with simulation devices, sites, pedagogy, and assessment rubrics. What was once an arcane and small niche activity has expanded enormously. Simulation can be thought of like playing a musical instrument: almost everybody can somehow coax a tone out of it, but to play it well and use it optimally can only come about after considerable practice.

This chapter aims to provide the reader—whether a simulation participant or a novice or experienced instructor—with a solid and nuanced understanding of many aspects of patient simulation in anesthesiology and other parts of health care.

Modern simulation with advanced teaching concepts and the integration of human factors training (CRM) is much more than traditional basic life support and advanced cardiovascular life support ("megacode") training. Modern simulation team training is academically demanding, personally stimulating, and involves many disciplines and lines of thinking. As a simulation instructor, you are operating at the core of our profession!

READERS WILL LEARN

- … about the varying uses of simulation in anesthesiology and health care, mainly focusing on the topics of training and education, research, system equipment probing, and assessment and evaluation.
- … to distinguish and classify different types of patient simulators (e.g., part-task trainers, simulators for low- and high-fidelity simulation, patient actors/standardized patients, hybrid simulation) and to understand their strengths and weaknesses.
- … about the possibilities and limitations of different simulation-based training approaches regarding (1) simulation site (e.g., dedicated simulation center, "in situ" simulation, mobile simulation); (2) simulation time (e.g., scheduled events vs. events on-call); (3) simulation participants (e.g., single discipline, multidiscipline, interprofessional).
- … about educational and psychological factors that enable or inhibit learning in patient simulation, such as scenario design and conduct, the elements or phases of a simulation training, and debriefing techniques.
- … about different multifaceted tasks of a simulation instructor and the need to acquire special skills to teach more complex and nuanced single-discipline or interprofessional activities.
- … about the ecological validity of simulation and what is known about its benefits, costs, and cost-effectiveness.
- … about the use of simulation for assessment of clinician performance and some of the issues and limitations thereof.

To cover those aspects, the authors have tried to balance retaining classic references, where the intellectual content has only changed slightly over the years, with newer ones that reflect either changes in thinking or evidence, or newer reviews and syntheses of knowledge and experience. Since simulation has become a key tool in addressing issues of patient safety and human factors in anesthesiology there is some degree of complementarity between this chapter and Chapter 6.

In this chapter, the authors use "anesthesia professional" to refer to any anesthesia clinician taking care of a patient, whether a physician, certified registered nurse anesthetist (CRNA), or anesthesia assistant (or to similar positions in other countries).

WHAT THIS CHAPTER IS NOT ABOUT

This chapter mainly addresses simulation in anesthesiology and presents the overall picture as seen by anesthesia professionals, intensivists, or others. Simulation devices and activities outside of the scope of perioperative management, that are strictly about psychomotor aspects of invasive procedures or surgery, and part-task screen-based simulators (e.g., Gasman) are at most only touched on briefly.

The chapter describes simulation in anesthesiology generically and does not address separately simulation for specific subspecialties. There is a sizable body of international experience with simulation in pediatric settings now that may be of further interest to some readers.[2-9]

Organizational aspects of simulation training and the topic of organizational implementation and sustainability of simulation programs are covered in Chapter 6, where simulation programs are covered from an organization's view among other organizational improvements to enhance patient and system safety. For more information on this topic, the reader is referred to the back part of Chapter 6 (Box 6.13 in Chapter 6 gives an overview).

Simulation in Anesthesia: Why Is It Important?

See one—do one—teach one? Read one—do one—teach one? Many decades ago anesthesiology trainees might have been "given a long leash" (inadequately supervised) and asked to gain experience by "sink or swim," often with a clinical population of indigent patients. Using actual patients in this way as if they are expendable "simulators" is unethical, and the presumed learning experiences were extremely uneven. In the last few decades unacceptable practices have been eliminated, but it increasingly begs the question of how can clinicians at all levels of experience feel the difficulties of patient care, including managing very difficult situations, without putting patients at undue risk? How does someone go from a total novice to a fully competent independent anesthesia professional? And of increasing importance, how can clinicians—during both initial and recurrent training—learn and hone skills of dynamic decision making, situation awareness, leadership, communication, and teamwork?

Anesthesiology is a "hands-on" discipline. It is not likely for medical students and residents to learn simply by "looking," "time passing," or by "osmosis." The application of (rare) technical skills, the correct use of medical knowledge and algorithms, as well as the reliable utilization of anesthesia nontechnical skills (see Chapter 6)—such as teamwork, communication, and leadership behavior—need to be learned and then trained repeatedly. At the same time, experience is no substitute for excellence (see Chapter 6). This is especially true for nonroutine events, such as emergencies or rare complications. Not only trainees but also experienced clinicians require continuous education and training of their clinical and nontechnical skills in order to stay current and avoid bad habits or the normalization of deviance (see Chapter 6).

Health care, with anesthesiology as the pioneering discipline, borrowed and adapted alternative educational approaches to teach knowledge and gain procedural experience from years of successful service in other industries that faced similar problems. These approaches focused on "simulation." Simulation is a technique well known in the military, aviation, space flight, and nuclear power industries. Simulation refers to the artificial replication of sufficient elements of a real-world domain to achieve a stated goal. The goals include for example education and training of technical and nontechnical skills, system probing, testing of equipment and supplies, and assessment as well as evaluation of students and personnel. These different topics are covered in this chapter, even though there is a focus on simulation as a training and education tool.

In 2000, the National Academy of Medicine (then the Institute of Medicine) released a report, *"To Err Is Human: Building a Safer Health System,"* that suggested the use of simulation training in health care in order to reduce preventable errors.[10] The American College of Critical Care Medicine recommended the use of simulation to improve training in critical care.[11] With anesthesiologists being the pioneers for simulation-based training in health care, simulation in anesthesia already has a long tradition. At the same time, its comprehensive and profound implementation has come a long and rocky way over the last decades and, despite many benefits, still needs further implementation and continuous evaluation. Major recognition of simulation in anesthesia by the clinical world is highlighted by the fact that it is now a highly utilized training course for the practice improvement component of Maintenance of Certification in Anesthesiology (MOCA) in the United States.[12] In Australia and New Zealand, it is an integral part of anesthetic training.[13,14] In their reviews, Lorello and colleagues, [15] LeBlanc and colleagues,[16] and Higham and Baxendale[17] give an overview of simulation-based training in anesthesia. In many parts of the world, including industrial countries, the use of simulation is way behind the United States or Australia.

A fundamental part of the future vision for simulation is that clinical personnel, teams, and systems will undergo periodic and systematic simulation activities across their entire career using various modalities of simulation and for diverse purposes of education, training, performance assessment, refinement in practice, and system probing. This vision is inspired in part by the systems in place in various high-reliability industries, especially commercial aviation and nuclear power (see Chapter 6). Needless to say, using simulation as part of the process of revolutionizing health care is more complex than merely attempting to stick simulation training on top of the current system. Moreover, beyond training, simulation may provide indirect ways to improve safety, including facilitating recruitment and retention of skilled personnel, acting as a lever for culture change, and improving quality and risk management activities.

Application of Simulation in Anesthesia and Health Care

Simulation techniques can be applied across nearly all health care domains.[18] A few books are devoted solely to the topic of simulation and its use in and outside of anesthesiology.[19-24]

In the upcoming section, an overview of the main objectives of simulation in health care and anesthesiology are presented in the following sequence: (1) education and training of technical and nontechnical skills, (2) system probing, (3) testing of equipment and supplies, (4) assessment/evaluation, (5) research, and (6) further purposes.

USE OF PATIENT SIMULATION FOR TRAINING AND EDUCATION

With respect to the first objective—education and training—anesthesiology remains a driving force in the use of simulation in health care,[25] although simulation has spread to nearly every discipline and domain. As used in this chapter, *education* emphasizes conceptual knowledge, basic skills, and an introduction to nontechnical skills and work practices. *Training* emphasizes preparing individuals to perform actual tasks and work of the job.

Disciplines successfully applying simulation for training besides anesthesia[15,26] are, for example, emergency medicine and emergency field responders,[27-29] trauma care,[30,31] neonatology[32-34] and pediatric anaesthesia,[2,3,5,35] labor and delivery,[36-38] surgery,[39,40] radiation oncology,[41] intensive care,[42,43] and infectious disease.[44,45] Simulation serves almost all resuscitation trainings, which have advanced over the years.[46] Fig. 7.1 gives several impressions of simulation training.

Nearly every anesthesia residency program in the United States offers some cogent simulation training experiences,

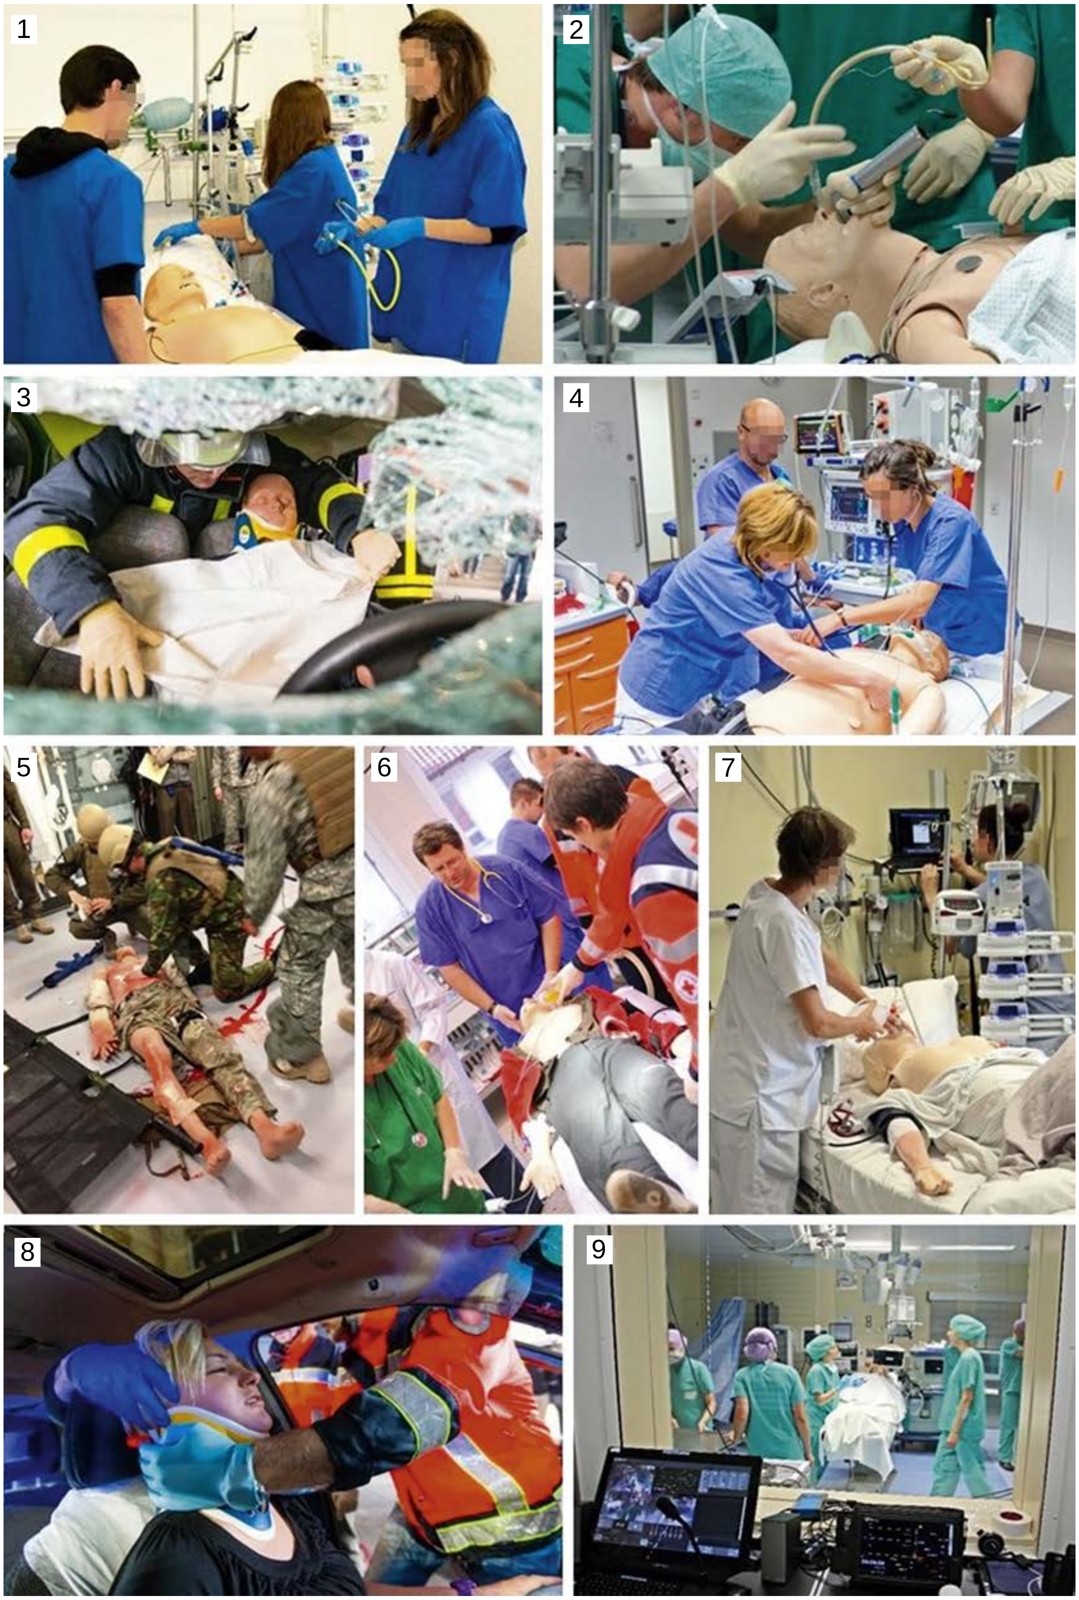

Fig. 7.1 Different impressions of simulation training sessions in different health care environments. Photos from left to right: (1) In situ simulation training on a ward. (2) In situ simulation team training in the anesthesia environment. (3) Simulation exercise during the annual simulation congress INSiM, Frankfurt Main, Germany. The photo shows a simulated patient that is rescued out of a crashed car. (4) Full-scale in situ simulation team training in the emergency department. (5) Military simulation training with Tactical Combat Casualty Training and Care under Fire conditions, *InPASS, Photo with permission by M. Rall.* (6) Simulation Training at the Simulation Center TüPASS in Tübingen, Germany. Shown is a handover moment where a traumatized patient is handed over from the ambulance team to the trauma team. *Photo with permission by director M. Rall 2010.* (7) Simulation training on the intermediate care unit. (8) Simulation exercise with a standardized patient that is rescued out of a crashed car. *Photo provided by M. Rall.* (9) In situ simulation training in an operating room (OR) showing the beginning of a full team obstetric scenario for emergency cesarean. The photo is taken through an OR window from the temporarily established simulation control room outside the OR. (*Photo provided by M. Rall.*)

although the scope, frequency, and target content vary. Other disciplines and other countries may not have adequate simulation training coverage during residency, as evidenced by a study by Hayes and colleagues.[47]

The military and the U.S. Department of Homeland Security also have been heavy users of simulation in health care; simulation has been applied to the initial training of new field medics and to the recurrent training of experienced clinicians and clinical teams.[48] In 2013, a first instructor course for the North Atlantic Treaty Organization (NATO) Special Operations Forces (SOF) was held at NATO headquarters in Brussels to bring together medical experts from the United States SOF, the NATO SOF, and some civilian instructor experts (including authors Rall and later Oberfrank).

Simulation is relevant from the earliest level of vocational or professional education (students) and during apprenticeship training (interns and residents), and it is increasingly used for experienced personnel undergoing periodic refresher training. Simulation can be applied regularly to practicing clinicians (as individuals, teams, or organizations; the latter for example for disaster drills, or for preparing to care for patients with Ebola virus disease[49]) regardless of their seniority, thus providing an integrated accumulation of experiences that should have long-term synergism. Thus, it is applicable to health care providers with a range of experience, including experts,[50] novices, advanced residents,[25] medical, nursing, other health care students,[51-57] and even children.[58-61] Simulation *rehearsals* are now being explored as adjuncts to actual clinical practice; for example, surgeons or an entire operative team can rehearse an unusually complex operation in advance by using a simulation of the specific patient.[62,63]

Many simulation centers offer continuing medical education (CME) and training for experienced practitioners, and many aspects of simulation training for residents can be expanded for this purpose. Several studies have shown that experienced anesthesiologists have deficiencies in the management of critical patient situations and make severe errors comparable to those of anesthesia residents.[64-71] Because crisis situations are rare during routine clinical work, these results are not startling. In addition, experience in terms of years on the job and hierarchy probably do not correspond to expertise and excellence. Crisis management training with patient simulation should be started early in education and training and applied on a recurring basis during practice.

Concerning education of health care professionals about patient safety, patient simulation can be a tool that contributes to changing the culture in an organization bottom-up to create a culture of safety. First, it allows hands-on training of junior and senior clinicians in practices that enact the desired culture of safety based on the principle of high reliability organizations (see Chapter 6).[72] Simulation can be a rallying point about culture change and patient safety that can bring together experienced clinicians from various disciplines and domains (who may be captured because the simulations are clinically challenging and show the need of change in direct relation to patient treatment), along with health care administrators, executives, managers,[73,74] risk managers,[75] and experts on human factors, organizational behavior, or institutional change. For these groups, simulation can convey the complexities of clinical work, and it can be used to exercise and probe the organizational practices of clinical institutions at multiple levels (see section on system probing). Various curricula and recommendations for curricula development for simulation training exist.[76-81]

USE OF PATIENT SIMULATION FOR SYSTEM PROBING AND PROTOCOL TESTING

In regard to the second objective, simulations that are conducted in actual patient treatment locations (referred to as "in situ" simulation, ISS) are powerful tools for testing (system probing) and evaluation of organizational practices (protocol testing).[75]

In a study comparing ISS to center-based simulations, ISS was related to more insights about processes in the organization and challenges with equipment.[82] Another study used simulation as a supplement to a Failure Modes and Effects Analysis (FMEA, see Chapter 6). In order to enhance system safety, FMEA is a risk management tool that proactively tries to enhance organizational learning by experts describing and identifying possible errors and their effects. Whereas adding simulation to that process did not result in more failure modes described, the process resulted in a richer description of how they would actually unfold in practice.[83]

Another way to probe the system is to identify active and latent failures during ISS of the treatment of patients. In Reason's famous error trajectory model to describe incident causation (known as the Swiss cheese model, see Chapter 6), incidents are seen as a combination of active (simplified: human) and latent (simplified: system) failures that interact to cause bad outcomes. Based on this model, a study[84] of 46 sessions of ISS training for handling emergencies was conducted with over 800 participants, with the goal to recognize and remedy active and latent failures in order to suggest where to invest resources. Of the total of 965 breaches, nearly 50% were classified as latent conditions, and the rest was classified as active failures. In another study, simulation was used to discover latent safety threats with the help of unannounced in situ simulation of critical patients in a pediatric emergency department.[85] Similarly, the "hemorrhage project" at Stanford assessed and trained the treatment protocol of life-threatening hemorrhage during several system-probing events using unannounced, simulation-based mock events, and successfully identified areas of improvement after probing.[75]

In 2016 simulation was used to demonstrate gaps in an organization's response system that could expose staff to Ebola once the emergency disaster response had been activated.[86] The simulation center had 12 hours to prepare simulations to evaluate hospital preparedness should a patient screen positive for Ebola exposure. Further simulation cycles were used during the next weeks to identify additional gaps and to evaluate possible solutions.

Furthermore, iterative simulation-based testing and redesign was shown to be of assistance when developing cognitive aids or protocols for all kind of crises, and to eliminate design failure. For instance, McIntosh and colleagues[87] used this approach to develop and test a new cognitive aid for the management of severe local anesthetic toxicity. Utilization of formative usability testing and simulation-based user-centered design resulted in a visually very different cognitive aid, reinforcing the importance of designing aids in the context in which they are to be used.

Simulation has a role in designing new hospitals and departments—whether in terms of the physical layouts or in terms of work processes. Simulation can help in evaluating design ideas. Simulation can be used to facilitate moving into a new location, for example moving with staff and patients into a new intensive care unit (ICU) or a new hospital.[88]

Simulation is increasingly appreciated as a tool for risk management. Driver, Lighthall, and Gaba[75] argue that from a risk management standpoint, simulation has a number of potential ways in which it might prevent claims or mitigate losses. They called simulation "*a data source about clinical performance*" [p. 356]. De Maria[25] and associates demonstrated that a simulation-based approach can identify system-wide practitioner gaps in anesthesiologists and create meaningful improvement plans.

USE OF PATIENT SIMULATION FOR TESTING EQUIPMENT AND SUPPLIES

With respect to the third objective—testing of equipment and supplies—patient simulation is being used in collaboration with biomedical industries. For example, some simulation centers offer training to executives, engineers, and sales representatives of equipment manufacturers. The simulator allows them to gain some understanding of the clinician's task demands during patient care situations (including those of unusual stress) in which their company's devices are useful.

Simulation has been used for research on human factor issues in the development of new monitoring and therapeutic devices. The simulator provides a unique test bed and demonstration modality for pre-procurement evaluation of the usability of medical devices from different manufacturers. In two of our affiliated hospitals (VA Palo Alto [DG] and Tübingen, Germany [MR]), simulation enabled us to conduct evaluations of prototype monitoring systems that were not yet approved for clinical use and could not be evaluated in a pre-procurement clinical trial.

Other industrial uses include training personnel in the use of novel pharmaceuticals. Simulators have been featured in a multifaceted approach to launch the opioid remifentanil in the United States and have been used to teach clinicians in the safe use of drugs, such as for example desflurane. Besides offering important educational benefits, industrial activities are an important source of income for simulation centers to help defray the costs of training students and residents.

USE OF PATIENT SIMULATION FOR PERFORMANCE ASSESSMENT

With respect to the fourth objective, simulations have taken a central role in the evaluation and assessment of the performance and competence of health care students, residents, practicing physicians, and teams—for low-stakes or formative testing (education and training), to a lesser degree to-date for summative testing (certification, recertification, etc.), and for research on clinician decision-making or on care processes. Assessment of performance for both clinical and nonclinical skills can be made in a variety of health care settings.[64,69,89-98]

Anesthesiology has taken a leading role in the development of simulation-based assessment.[99] In a review study in 2012, Boulet and Murray[99] summarized simulation-based assessment for education specifically in anesthesia. In a more recent systematic review in 2016, Ryall and colleagues[100] summarize the use of simulation as an assessment tool of technical skills across health professional education. They concluded that simulation is an effective assessment tool, but pointed out that the effectiveness as a stand-alone assessment tool requires further research.

Assessment with simulation held and still holds several challenges for research and education. Those include: (1) to determine aspects of performance to be measured, (2) to create reliable and valid scores and measurement tools, and (3) to find measures for both clinical and nonclinical performance. Furthermore, simulation itself poses several unique challenges and pitfalls that need to be taken into account, as discussed later in this chapter. Several assessment measures and scoring systems exist.[99-102]

Organizationally, in the United States, the Accreditation Council for Graduate Medical Education made the use of simulation a required component for anesthesiology residency programs. Recognizing its benefits not only for education and teaching of novices and residents, but also for the continuous education of certified practicing anesthesiologists, more recently simulation-based training in managing challenging situations leading to practice improvement was adopted as a favored component of the American Board of Anesthesiology's (ABA's) MOCA program. Whereas simulation as a tool for the formative assessment of performance during training of students and residents is already widely used in anesthesiology, it has still penetrated only modestly for the formative assessment (and less so for summative assessment) of practicing anesthesiologists,[103] raising new questions as described in a study by Weinger and colleagues.[64]

Because performance assessment is closely related to human performance, many results of simulation studies with this focus were already discussed in Chapter 6, and the reader is referred there as well.

USE OF PATIENT SIMULATION FOR RESEARCH

In regard to the fifth objective—research—simulation-based research falls into two categories: (a) research *about* simulation—testing or improving the techniques, technologies, and didactics of simulation; and (b) research *that uses* simulation as a tool to study other things, such as human performance and clinical cognition (see Chapter 6), or clinical care processes.[104] Box 7.1 provides a sampling of these types of questions.

Regarding research about simulation, some examples would include the design of debriefing approaches such as Debriefing with Good Judgement,[105-107] Debriefing-Diamant,[108] PEARLS,[109] TeamGAINS,[110] and others[111-114]; methods for designing simulation scenarios such as PARTS[115]; the efficacy of using videos in debriefings[116-120]; the creation and maintenance of an inviting learning atmosphere[121]; the effective design of specific training interventions such as for resuscitation,[46,122,123] airway

BOX 7.1 Exemplary Research Issues That Can Be Addressed by Using Simulation

Cognitive Science of Dynamic Decision Making (see Chapter 6)

- What is the interaction of precompiled procedural knowledge (Type I thinking) versus deep medical knowledge and abstract reasoning (Type II thinking)?
- How does supervisory control of observation relate to vigilance, data overload, and visual scanning patterns?
- What is the information content and utility of watching the surgical field?
- How are optimal action planning and scheduling implemented?
- How does reevaluation fail and result in fixation errors?

Human-Machine Interactions

- What is the distraction penalty for false alarms?
- Do integrated monitors and displays have an advantage over multiple stand-alone devices and displays?
- How easy to use are the controls and displays of existing anesthesia equipment in standard case situations and in crisis situations?

Teaching Anesthesia in the Operating Room (see Chapter 6)

- How much teaching can be accomplished in the operating room without sacrificing the anesthesia crew's vigilance?
- How well can faculty members detect and categorize the performance of anesthesia trainees?
- What teaching styles are best integrated with case management in the operating room?

Issues of Non-Technical Skills/Teamwork on Anesthesiologist Performance

- How does an anesthesia crew interact during case and crisis management?
- How is workload distributed among individuals?
- How do crew members communicate with each other, and how do they communicate with other members of the operating room team?

Effects of Performance-Shaping Factors on Anesthesiologist Performance

- How do sleep deprivation, fatigue, aging, or the carryover effects of over-the-counter medications, coffee, or alcohol affect the performance of anesthesiologists?
- Can smart alarm systems or artificial intelligence provide correct and clinically meaningful decision support in the operating room or intensive care unit?

Development of New Devices and Applications: Research Regarding Techniques of Simulation

- How well can simulations re-create perioperative clinical settings? Can they provoke the same actions as used in real clinical care (ecologic validity of simulators)?
- How much does debriefing add to learning from simulation? Are specific techniques of debriefing, or combinations thereof, of greater applicability or utility, overall or for particular situations?
- How do various aspects of simulation scenarios influence aspects of perceived reality, and how do they influence transfer of training into the real world?
- Does simulation training lead to better clinical practice and improved clinical outcomes?

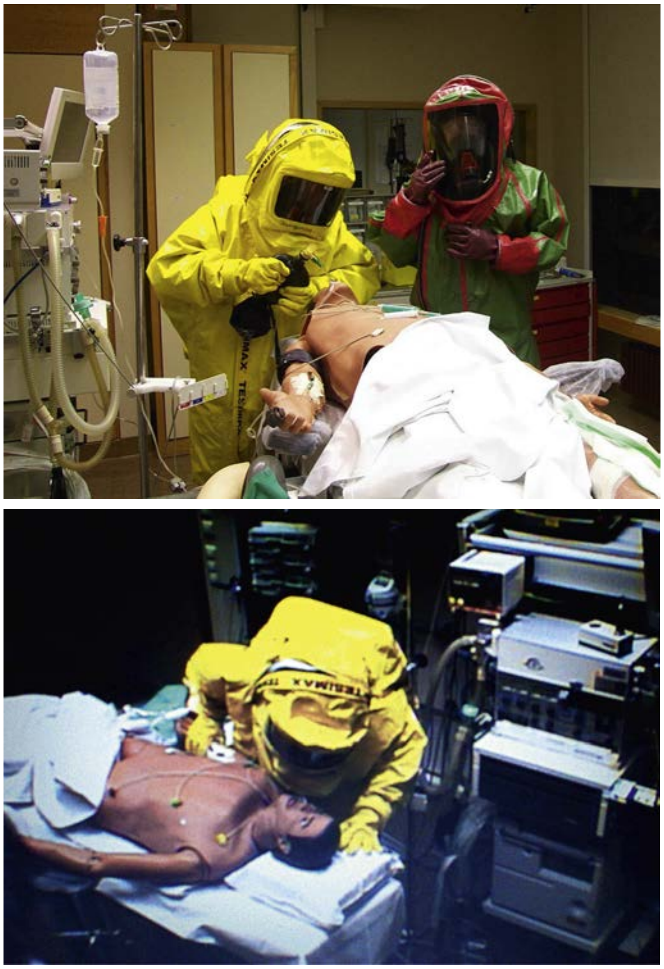

Fig. 7.2 Realistic patient simulation as a test bed for studying the performance of medical rescue teams in full chemical protection gear. Teams wore normal uniforms or full protection suits while performing basic resuscitation actions (e.g., placement of intravenous lines, drawing up drugs, intubation). With full protective gear, communication within the team and with the patient (while still conscious) is difficult. (*Photograph taken by M. Rall at the Center for Patient Safety and Simulation, Tübingen, Germany.*)

management,[124,125] and avoidance of catheter-related infections[126]; and testing of specific training interventions such as for facilitating speaking up,[50,127-129] briefings, [130] and feedback.[131]

Patient simulation is now used sometimes to address the medical management of chemical, biologic, or nuclear threats from accidents, weapons of mass destruction, or terrorism. One group in Germany, used simulation to test the constraints of treating patients in full chemical protection gear to optimize the strategies of the German Ministry of Internal Affairs for dealing with terror attacks or chemical plant disasters (Fig. 7.2). Several investigators have performed multidisciplinary studies with combined simulation modalities (script-based simulators, model-based mannequin simulators, and simulated acted patients) to teach the management of victims of an attack with weapons of mass destruction and terrorism.[132,133] The demand for such training is substantial in nations engaged in active military conflicts or with an ongoing need to prepare for war or terrorist attacks.

Regarding (b) simulation as a research tool, it offers some unique features, and it can be thought of as a complementary window on the clinical world relative to other modalities. It can be applied, for example, when complex phenomena such as medical team processes are studied. Examples are investigations of how teams adapt from routine to non-routine situations and how this adaptation is related to performance,[134-140] communication processes such as information processing,[141] talking to the room[142] and speaking up,[50,129,143-146] problem-solving and decision-making,[142,147-149] and coordination requirements during resuscitation.[139,140,150-154] Important milestones for simulation-based research of both types was the creation by the Society for Simulation in Healthcare (SSH) in 2007 of its flagship peer-reviewed journal, *Simulation in Healthcare* followed in later years by other peer-reviewed journals (e.g., *Advances in Simulation, BMJ Simulation & Technology Enhanced Learning, Clinical Simulation in Nursing*). In addition, for research that is linked tightly to a specific clinical domain, the traditional medical specialty journals have become more welcoming to articles about simulation or that use simulation as an experimental technique.

Cooperation between simulation directors or instructors and psychologists, human factors engineers, or educators has proved useful in research and training. Such collaborations have helped delineate the theoretical foundations of simulation-based experiential learning, improve the understanding of debriefing, and research on work psychology and human performance in health care.[155-161] Many institutions have integrated psychologists or educators, or both, into their simulation center staff.

OTHER USES OF PATIENT SIMULATION

Traditionally, simulation-based training is focused on health care professionals as the recipients. In recent years, simulation was opened up for new types of recipients. These studies are not conducted within anesthesia, but demonstrate innovative ways of thinking about simulation that might be adaptable in some form to anesthesia-oriented simulations. A study showed that the use of "standardized clinicians" to train patients to be more competent in their discharge conversations was feasible.[162] Patients interacted with role players in the role of the discharging clinician, practicing what to say and ask, as well as how to manage the medication they were supposed to take. The group around Kneebone involves patients in the design of simulations, opening simulation activities to them.[163] They use simulation in a demonstration mode that intends, for example, to give citizens an improved insight into what it is like to be in the hospital[164,165] or what care in the clinical context should feel like.[166] The aim is to diversify access to simulation beyond health care professionals.

Other unique applications of simulation have surfaced. Some centers use simulators for conducting outreach programs with high school or college students interested in health care. Patient simulators have been used to help produce educational videos on various patient safety issues. Simulation has sometimes been used to familiarize legislators or regulators with the realities and complexities of dynamic patient care.

Simulation has been used as adjuncts in medicolegal proceedings.[167] While current patient simulators cannot predict the exact physiologic behavior of a specific patient, simulations can be used to illustrate typical perioperative situations and the role of different monitors and therapeutic actions and to provide context for the patient management questions of the litigation.

The use of simulation training for strategic or operational coordination and decision making in health care logistics has been described.[168]

History, Development, and Types of Simulators and Simulation

The following section gives a short, non-exhaustive overview about the history and the development of the main simulators in health care and anesthesia. For a more in-depth examination of the topic, the reader is referred to further literature. Particularly the mannequin-based simulators that are in wide use have been well covered in several review articles[169-171] and a whole book chapter by Rosen written in 2013 is dedicated to the topic in detail.[172] Another comprehensive textbook on the history of simulation in health care tracing it back 1500 years was published by Owen.[173]

Simulation probably is as old as mankind. Simulation has probably been a part of human activity since prehistoric times. Rehearsal for hunting activities and warfare was most likely an occasion for simulating the behavior of prey or enemy warriors. In medieval times soldiers learned the art of swordsmanship on dummy soldiers. Hundreds of years ago, models were used to help teach anatomy and physiology, and simulators were used to train surgical procedures and to help midwives and obstetricians handle complications of childbirth. Italy was the major source of simulators early in the 18th century, but in the 19th century, dominance in clinical simulation moved to France, Britain, and then Germany.[174] In modern times, preparation for warfare has been an equally powerful spur to the development of simulation technologies, especially for aviation, navy and armored vehicles. These technologies have been adopted by their civilian counterparts, but they have attained their most extensive use in commercial aviation. The aircraft simulator achieved its modern form in the late 1960s, but it has been continuously refined.

Mannequin-based simulators (MBSs). In 1969, the first electromechanical mannequin-based simulator in modern health care—Sim One—was produced by an aerospace company working with an educator and an anesthesiologist at the University of Southern California.[175] It consisted of a mannequin comprising an intubatable airway and upper torso and arms, and in many respects was years ahead of its time. It was originally used as an aid for students or residents learning to intubate, as well as to induce anesthesia but the project died out in the early 1970s. In the following years, several other mannequin-based patient simulators were developed and introduced in the middle to late 1980s. Noteworthy among others is Harvey, a cardiology mannequin simulator released in 1976, which is able to simulate the arterial pulse, blood pressure, jugular venous wave, precordial movements, and heart sounds in normal and diseased states.[176] In 1986, a team at Stanford, headed at first by Gaba and DeAnda,[177] developed a full-scale simulator called the Comprehensive Anesthesia Simulation Environment (CASE); they used it initially to study the decision-making processes of anesthesia professionals during critical events,[68,178,179] but they were also interested in its use for training. Over a few years, with their recognition of the parallels with Crew/Crisis/Cockpit Resource Management (CRM) in aviation this team developed their flagship simulation training course Anesthesia Crisis Resource Management (ACRM, see Chapter 6).[180,181] Newer commercially-available mannequin-based patient simulators have been in use in anesthesiology since about 1995, and considerable collective experience with the devices already has been achieved. Currently, full-size mannequin-based simulation devices are used in most simulation centers (available now, for example, from the manufacturers Laerdal, Gaumard, CAE Healthcare, and others). Such devices allow the simulation of rapidly changing physiology and can support a variety of hands-on interventions (e.g., airway management, vascular cannulation, drug administration, electric countershock, or pacing). Some devices allow the system automatically to recognize injection of specific medications or therapeutic maneuvers, such as cardiac massage, and then—with or without instructor input—to respond in an appropriate manner.[182] Even though highly developed, mannequins still miss important features. Box 7.2 shows desirable features of future MBS systems.

PATIENT SIMULATION ACTION BOX

From a patient safety and teaching point of view, it is a mistake to focus too much on complicated and nice-to-have features that the latest device might offer. Those features and add-ons will not necessarily improve simulations or benefit participants. High-fidelity simulation may be useful, but that will not necessarily require a simulation device with complex features. It is critical pedagogically, and economically, to match the simulation device to the target population and objectives of the simulation activity.

(Computer) Screen-based simulators (microsimulators). Beginning in the mid-1980s, several screen-based, also called screen-only simulators (microsimulators), were developed by anesthesiologists. These included (1) screen-based part-task trainers that simulated isolated aspects of anesthesia, such as the uptake and distribution of anesthetic gases in the body given different physiologic and physical chemistry situations (e.g., the well-known Gasman program[183]); and (2) screen-based overall-task trainers that represented nearly all aspects of the patient and clinical environment. Originally, the patient was represented by drawings or animations, but increasingly in these systems the representation of the patient is by photographs or videos. Vital signs appearing on virtual monitors may mimic real clinical devices. Actions are selected typically using a graphic user interface, pointing and clicking on menus and buttons, and using sliders and numeric entry boxes to allow control of most kinds of interventions that clinicians use on a regular basis.

BOX 7.2 Desirable Features of Future Mannequin-Based Simulator Systems

- Ability to interface to or to mimic advanced brain monitoring such as: *AEP,* Auditory evoked potential; *BIS,* bispectral index; *EEG,* electroencephalographic; *PSI,* patient state index.
- Advanced skin signs such as: change in skin color to cyanotic or pale, improved diaphoresis, change in skin temperature (e.g., as a result of shock or fever), rash, hives, or generalized edema
- Regurgitation, vomiting, airway bleeding or secretions
- Physical coughing (currently only sounds are simulated)
- Realistic convulsions
- Purposeful movements of extremities
- Improved or possible support for spinal, epidural, or other regional anesthesia procedures
- Improved EEG signals (e.g., for BIS, AEP, PSI)
- Improved intracranial pressure
- Support for physical central venous and arterial cannulation
- Improved fetal and maternal cardiotocogram

Please note: *This list contains features that are not currently incorporated. Some features may be under development and could be available after publication of this book. In addition, some features are currently available as third-party or homemade add-ons.*

Part-task trainers and virtual procedural simulators. In the 21st century, advancements in engineering and computer science have stimulated a new era of simulator technology, including:

- Part-task trainers in the form of anatomic mock-up devices that are made from synthetic material to represent human body parts, such as models that allow training of central line placement, epidural catheter insertion, cricothyroidotomy, or chest drainage. Over several decades, tissue-based simulation—representing some sort of part-task trainer—has become more common, with trainees no longer learning procedural skills using animal models because of cost and issues of animal rights.
- Virtual simulators for surgical and procedural skills (i.e., hardware and software that provide haptic feedback for performing realistic laparoscopic cholecystectomy, bronchoscopy, colonoscopy, echocardiography, and endovascular procedures).[182] In these systems, the synthetic (virtual) environment exists solely in the computer. The real procedure is performed by using a video display that can be recreated by the simulator. The person simulating the procedure interacts with the video display through the eyes (without or with head-mounted glasses) and the ears, and usually the hands, if the simulator features special instruments, instrumented gloves, or sensors. For anesthesia, for example, there exist VR simulators to train the conduct of fiberoptic intubation[184,185] and regional anesthesia.[186,187] Two systematic reviews are available for more in-depth information on the general use of simulation teaching regional anesthesia.[188,189]

Virtual reality and augmented reality (usually via head-mounted displays). Both immersive *virtual reality* (VR), which fully integrates the human user into the computer's world, and *augmented reality* (AR), which adds computer-generated imagery onto or next to the real-world view, typically use head-mounted displays to either replace ordinary vision or to augment it. Both approaches have been described in the literature, often in prototype or research-only settings. This chapter will discuss only VR and not AR. The authors (DG in particular) have been evaluating commercially available systems for head-mounted display VR. For health care they seem to fall into two categories: (1) *visualization* of objects or spaces—typically for anatomical structures, or for architectural environments, and (2) *physically interactive clinical environments*—meaning the clinicians themselves can move with the space and interact directly with each other and the virtually presented patient, essentially the VR equivalent of physical mannequin-based simulation. Visualization applications are much more common and are direct applications of consumer VR hardware and software (e.g., visualizing the human heart in all its detail inside and out instead of, say, the Taj Mahal). Fully interactive VR makes use of commercial head-mounted displays and other gear but is more complex to create the clinical space, patient, and equipment while providing for multiple physical participants to interact with seamless head and body movements.

Both types of VR are still in quite early stages of practical implementation in health care and how these approaches can best be used in health care remains to be seen, but the tide is now turning away from arcane research or "vaporware" to an era of rapidly improving practical devices and applications. Although Gaba has previously written that VR would soon (by 2020-2025) completely replace all physical simulation, this now seems unlikely in that time frame; in fact, it is likely that VR will join the spectrum of simulation modalities each of which has a set of unique advantages and disadvantages relative to the others.

Virtual Environment/Virtual World. A related type of virtual simulation is the *virtual environment* or *virtual world.* According to Wikipedia, a virtual world is a computer-based simulated environment intended for its users to inhabit and interact through avatars (users' graphic representation of themselves). Such systems typically allow multiple participants to control their own avatars (including speech) simultaneously over a network and to interact verbally and by virtual physical actions within a commonly perceived virtual environment. This technology currently portrays the virtual world as perspective three-dimensional images (or possibly true 3D) on a computer screen with sound. Virtual worlds are most commonly used for computer games. In a medical virtual world, the patient may be an automated avatar controlled by the computer, or the patient may be an avatar inhabited by a human participant. Kleinert and colleagues published a review of such systems in 2015 and concluded that the development and validation of such simulators will need to be the subject of further research.[190]

Standardized patients. Standardized patients (SPs; in some countries referred to as "simulated patients") are actors/role players who are trained to represent a patient's condition (e.g., symptoms or social situation) and may be trained to score a participant's performance and to provide informative feedback. Over the last three decades, students increasingly learn skills in medical history taking and physical examinations using SPs.[170] Overviews of the use and implementation of SPs in anesthesia education are available.[191-193] SP-based simulations are increasingly being used for issues such as disclosure of bad news and other difficult conversation as well as in pain medicine. [194]

Hybrid simulation. Hybrid simulation means combining different types of simulation modalities during a simulation scenario. It can be used in different ways and serves several purposes: (1) *Pairing simulation devices in parallel.* This way, a training atmosphere can be established, in which different professions can have credible clinical work for their role. For example, when training the management of complications in the OR with surgeons and anesthesiologists together, it is helpful if both professions have clear functions during the scenario. For example, Kjellin et al. performed a multidisciplinary OR team training, where training was performed in a mock-up OR equipped with a mannequin-based patient simulator and a laparoscopic simulator.[195] Another option is to integrate manufactured life-like surgical models with the mannequin, as used by Weller et al. for multidisciplinary OR team training.[14] (2) *Pairing simulation devices in sequence.* This way, the best characteristics of each simulation modality can be used in a scenario and create a simulation that is more than the sum of the parts. For example, a scenario can start with a standardized patient/role player presenting in a patient bed or gurney; the simulation can be transferred to a mannequin at a critical point, such as when invasive activities are needed (e.g., intubation or CPR) or when giving birth. Cantrell and Deloney offer suggestions for integrating SPs into high-fidelity simulation scenarios.[192]

Simulation Fidelity and Classification of Simulators

Simulation is becoming more commonly used for education and training purposes as well as for continuing professional development. But people often have very different perceptions of the definition of the term simulation. This highlights the need for definitions of simulation modalities, simulation fidelity, a classification of the relevant technologies and features, and also a brief overview about the methods of teaching.

Simulation fidelity and simulator capability. In the simulation literature the term fidelity—which means how closely something replicates reality—is often used to refer to specific devices or products. In contrast, the authors believe strongly that this is a misnomer and that the concept of fidelity is a property of the simulation *activity* and not primarily of the device(s) or

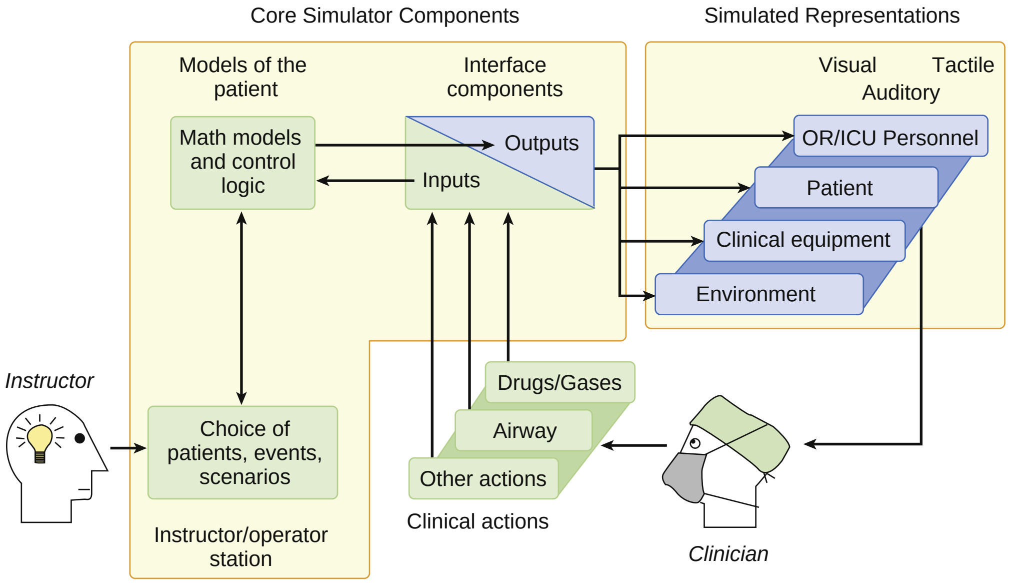

Fig. 7.3 Schematic diagram of the generic architecture of patient simulator systems. The simulator generates a representation of the patient and the work environment with appropriate interface hardware, display technologies, or both. The representation is perceived by the anesthesia professional, whose actions are input to the simulator through physical actions or input devices. The behavior of the simulated scenario is manipulated by the instructor or operator through a workstation that allows selection of different patients, abnormal events, and other features of the simulated patient. The control may be manual, script based, or model based with manual adaptation to reach optimal learning outcomes. *ICU*, Intensive care unit; *OR*, operating room. (*Diagram by D.M. Gaba.*)

products used. That is, fidelity is determined by the number of aspects that are replicated by the simulation (not only physical ones) and the applicable representation of each aspect relative to that of the real world (see subchapter on simulation realism). The fidelity required of a simulation depends on the stated goals and participant population. Some goals can be achieved with minimal and low fidelity, whereas others require very high fidelity.

Classification of simulators. For some purposes it is useful to compare the levels or specifics of the particular technological *capabilities* of simulator devices. There is no universally accepted classification scheme for describing simulators in anesthesia.[169] Any classification involves some overlapping and gray areas.[159] Cumin and Merry describe a classification that is based on the three pillars of (1) user interaction, (2) physiology base, and (3) use.[196] Gaba[171] classifies simulation modalities according to the following scheme: verbal simulation (i.e., "what-if" discussions, storytelling, trigger videos, role playing), SPs, part-task trainers (including realistic mock-up devices and tissue simulation), computer patient (i.e., VR simulation, microsimulators/screen-based simulators), and electronic patient.

In this chapter, a *patient simulator* (as opposed to a part-task trainer) is a system that presents an approximation of a whole patient (not only parts of it) and a clinical work environment of immediate relevance to anesthesiologists (e.g., operating room, postanesthesia care unit, ICU, etc.). A patient simulator system contains several components (Fig. 7.3).[159] Some of the currently available features of typical mannequin-based patient simulators are presented in Table 7.1.

In the following, the major education and teaching purposes of main simulator classifications are presented. The presentation is partly based on the idea of the Miller prism (also pyramid or triangle) of clinical competence. For a more elaborate overview the reader is referred to further literature.[75]

Miller's learning pyramid. For each simulation a variety of different learning objectives exist. Largely they can be aligned to the Miller pyramid[197] shown in Fig. 7.4. On the cognition level, simulations can be used to help learners acquire new knowledge and to better understand conceptual relations and dynamics ("knows," "knows how"). For example, physiologic simulations allow students to watch cardiovascular and respiratory functions unfold over time and how they respond to interventions—in essence, bringing textbooks, diagrams, and graphs to life. The next step on the spectrum is acquisition of isolated skills to accompany knowledge ("knows how," later "shows how"). Some skills follow swiftly from conceptual knowledge (e.g., cardiac auscultation) while others involve intricate and complex psychomotor activities (e.g., catheter placement or intubation). Isolated technical and non-technical skills must then be assembled into care processes and existing workflow concepts, creating a new layer of clinical practices ("shows how," later "does"). Over time those assembled skills get integrated into practice and become part of daily performance ("does"). The expert health care professional performs only in the "does" triangle, except when honing old skills or learning new ones. However, there may be a gap between the level of performance that individuals—or teams or work units—"do" compared to the optimal level. Often, clinicians might be able to demonstrate

TABLE 7.1 Functionality of Typical Current Mannequin-Based Simulator Systems*

Clinical Area	Features and Functions	Remarks
Airway	Appropriate pharyngeal and glottic anatomy	The airway often provides an acceptable seal for ETT; the seal for supraglottic airway devices can be variable, but it generally does allow positive pressure ventilation. The facemask seal is variable (plastic on plastic)
	Placement of facemask, ETT, supraglottic airway devices, Combitube	
	Laryngospasm, tongue and airway swelling, cervical immobility, jaw closure, breakable teeth	
	Cricothyrotomy	Cricothyrotomy of modest anatomic realism; the tissue does not feel like real skin and lacks a subcutaneous fat layer; no bleeding occurs; however, the simulation does allow going through the physical steps of inserting a subglottic surgical airway.
	Transtracheal jet ventilation	
	Bronchial anatomy (to the lobar bronchus level)	
Head	Eyelid movement, pupil dilation, and reaction to light or medications	
	Patient voice and sounds such as coughing and vomiting (through built-in loudspeaker)	A live voice is preferred to the prerecorded audio clips because of higher flexibility in scenarios.
	Palpable carotid pulses	
	Cyanosis represented by blue light at the edge of the mouth	The blue light is a cue that the patient is cyanotic, but it does not physically replicate the appearance of cyanosis.
	Tearing, sweating	
Chest	Physiologic and pathophysiologic heart and breath sounds Spontaneous breathing with chest wall movement	Breath and heart sounds through loudspeakers; sounds contain artifacts and mechanical noise. Often sound level depends on position of stethoscope relative to loudspeaker.
	Bronchospasm	
	Adjustable pulmonary compliance	
	Adjustable airway resistance	
	Pneumothorax	
	Needle thoracotomy and chest tube placement	As for cricothyrotomy the anatomy is not very realistic, but the mannequin may allow performance of these procedures.
	Defibrillation, transthoracic pacing ECG	
	Chest compressions	
Extremities	Palpable pulses (dependent on arterial pressure)	
	Cuff blood pressure by auscultation, palpation, or oscillometry	
	Modules for fractures and wound modules	
	Intravenous line placement	
	Thumb twitch in response to peripheral nerve stimulation	
	Arm movement	Most current simulators do not provide even limited robotic movement of limbs.
	Representations of tonic-clonic seizure activity	These representations are cues that lack anatomic reality.
Monitoring (waveforms or numeric readouts)	ECG (including abnormalities in morphology and rhythm) SpO_2	Most simulators provide a simulated virtual vital signs display; some can interface to actual clinical monitors.
	Invasive blood pressure	
	CVP, PAP, PCWP	
	Cardiac output	
	Temperature	
	CO_2 (may be actual CO_2 exhalation)	
	Anesthetic gases (may have actual uptake and distribution of agents)	
	Cardiopulmonary bypass	Some simulators include(d) a virtual cardiopulmonary bypass machine.
Automation and sensors	Chest compressions Ventilation rate and volume	
	Defibrillation and pacing (including energy measurement)	
	Gas analyzer (inspired O_2, anesthetics)	
	Drug recognition (drug identification and amount)	

CO_2, Carbon monoxide; *CVP*, central venous pressure; *ECG*, electrocardiogram; *ETT*, endotracheal tube; *O_2*, oxygen; *PAP*, positive airway pressure; *PCWP*, pulmonary capillary wedge pressure; *SpO_2*, saturation of peripheral oxygen.

*The features listed are each present in some existing simulators, but not all features are present on any single device. Sets of features depend on the device and model.

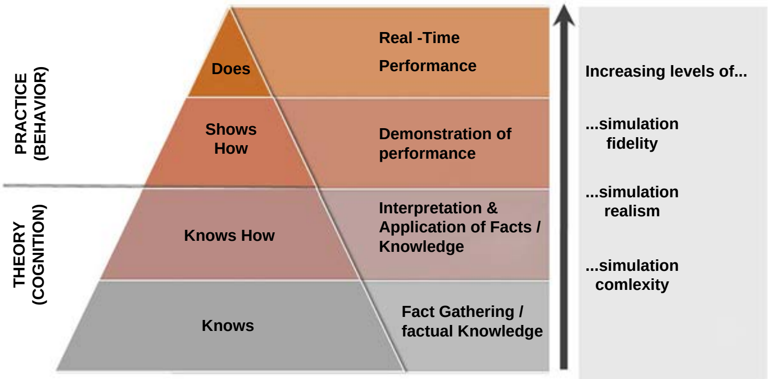

Fig. 7.4 Miller's learning pyramid, also known as Miller's prism of clinical competence.[197] Based on the Miller's learning pyramid, the clinical competence of an anesthesia professional is built on four different competence levels, that can be divided into theory (a person's cognition: "knows"-"knows how") and practice (a person's behavior: "shows how"-"does"). The most relevant clinical competence is the real time performance ("does"). Those four levels need to be considered when addressing learning goals as well as assessment goals of simulation. The figure is modified from a publication of Alinier,[368] indicating that simulation fidelity, simulation realism, and simulation complexity increase with different levels of competency.

"knows how"—"shows how" without necessarily being able to "do" under all relevant circumstances and occasions. Simulation can be a valuable tool to close such gaps.

PATIENT SIMULATION ACTION BOX

In the current health care system, for most invasive procedures, novices' first time performing a task is on a real patient, albeit under supervision, and similarly they will then climb the learning curve by working on real patients. Simulation offers the possibility of having novices practice both before their apprenticeship-like work as well as honing those skills with simulation in parallel with their clinical experiences. This is especially useful because simulation lets them gain experience even with uncommon anatomic or clinical presentations.

Non-technological simulation. Verbal simulations ("what-if" discussions), storytelling, paper and pencil exercises, and experiences with SPs require little or no technology, but can effectively evoke or recreate challenging clinical situations. Similarly, even pieces of fruit or simple dolls can be used for training in some manual tasks. Some education and training on teamwork can be accomplished with role playing or discussion of videos of relevant events.

(Computer) Screen-based simulators (microsimulators) that present the patient on the screen as drawings, photos, or videos, while allowing clinical actions or changes to be chosen can be used to teach basic concepts and technical material, such as the uptake and distribution of inhaled anesthetics or the pharmacokinetics of intravenous drugs. Such programs are inexpensive and easy to use. They allow the presentation of and practice with the concepts and procedures involved in managing normal and abnormal case situations, mostly targeting the parts of the Miller pyramid referred to as "knows" and "knows how," commonly for early learners.

Part-task trainers include artificial (and occasionally animal or human cadaver) models used to teach particular procedural skills, for example intubation, intravenous or intraosseous access, regional anesthesia techniques, thoracic drainage, and use of difficult airway management devices. These target "knows how" and "shows how." Such trainers are most commonly used with novices having little experience with the procedure, or to retrain experienced personnel in the application of the particular tools.

Mannequin-based simulators, representing most or all of a patient, can be used to capture the full complexity of the real task domain, including application of clinical skills and clinical algorithms in combination with human-machine interactions and the complications of working with multiple personnel. They can be used to address "shows how" extending into "does," at least in simulation (see later section on translational research levels). Therefore, MBS are appropriate to teach diagnosis and management of challenging situations as well as non-technical skills and human-factor-based behavior (see Chapter 6). These can be used, with different educational approaches, for all levels of learners. For early learners it is common to use a teacher in the room as an advisor or coach, and to control the simulation by "pause and reflect" allowing the scenario to be stopped and continued or restarted as necessary to maximize their learning.

PATIENT SIMULATION ACTION BOX

Compare to Miller's learning pyramid: If participants are not (yet) familiar with the clinical concepts, procedures, or tasks needed for the mannequin-based training, they should usually be taught those in other ways prior to full-scale simulation.

TABLE 7.2 Site of Simulation and the Related Advantages and Disadvantages

Site of Simulation	Advantages	Disadvantages
Dedicated center *(fixed facility not part of an actual clinical work unit)*	■ Equipment permanently installed, minimized setup time, high level of control and infrastructure ■ Facilitated use of complex audiovisual systems ■ Facilitated conduct of detailed debriefing of simulation involving video review ■ Ease of scheduling ■ No interference with actual clinical work, protects personnel from being pulled into real clinical work ■ Multipurpose use	■ Inability to recreate exact work unit, equipment, supplies of diverse target populations ■ Possible difficulties for clinicians to be off duty to attend training ■ Personnel not readily available for clinical work ■ Eventually remote from site of clinical work ■ Creating and maintaining a dedicated simulation center is expensive ■ Does not probe actual clinical setting
■ Temporary in situ simulation *(Actual work unit; temporary setup and takedown)*	■ Real clinical site ■ Probing/training of personnel in their actual work unit, using real equipment/supplies ■ Ready ability for clinicians to attend in proximity to their work ■ Probes actual clinical site(s) and system(s) ■ Less expensive than operating a dedicated simulation center	■ Vacant clinical space is not always available ■ Difficulties in scheduling—may need site for clinical use ■ Possible interference with actual clinical work; personnel readily drafted to return to clinical work ■ Distractions from onlookers is hard to control ■ Minimal audiovisual system, less audio-video recording capability ■ Great effort of setup and takedown
■ Residential in situ simulation *(Actual work unit; permanent facility)*	■ Same as temporary in situ ■ Minimized setup time ■ Complex audio-video system available ■ Easy scheduling	■ High cost of creating a permanent simulation bed in a clinical work unit ■ Possible interference with actual clinical work; personnel readily drafted to return to clinical work ■ Distractions from onlookers is hard to control
■ Peri-situ/off-site simulation *(simulation in a nonclinical environment such as a conference room, etc.)*	■ Good to schedule ■ Simulation can be used without clinical space or a dedicated simulation center needed ■ Every training is better than no training ■ Many supplies and some equipment can be used as if it was the real thing	■ Lack of ideal realism of bedside or in situ training ■ Minimal audiovisual system, less audio-video recording capability ■ Great effort of setup and takedown ■ No system probing
■ Sequential location simulation/“moving simulation” *(simulated transport of simulator from site to site)*	■ The challenging clinical work of transport itself ■ Replication of natural flow of patients and handoffs between teams	■ Requirement for multiple simulation sites ■ Technologic limitations of portable wireless simulators ■ Great effort of setup and takedown
■ Mobile simulation *(travel of simulation systems and instructor crew to client or neutral sites)*	■ Simulation expertise brought to those who cannot or wish not to invest in it themselves ■ For in situ use, all advantages thereof	■ Possibly high transport costs (driver, fuel, vehicle) ■ For in situ use, all disadvantages thereof plus even greater effort for setup and takedown

PATIENT SIMULATION ACTION BOX

Regardless of the device used, the simulator is only a teaching tool that must be coupled with an effective curriculum for its use.[198] The more complex simulations get (i.e., MBS) and the more a simulator represents a whole patient—to be treated by one or more teams—the more it is important to have qualified instructors with special training.[198]

Sites of Simulation

Some types of simulation such as nontechnological ones and those that use videos or computer programs can be conducted in the privacy of the learners' home or office using their own equipment. Part-task trainers and mannequin-based simulation are often used in a dedicated simulation center, but MBS is increasingly also done “in situ” (in place)—in a real patient room/bed—or “peri-situ” (near the place)—nearby elsewhere in the clinical work unit. For large-scale simulations (e.g., disaster drills[49,86]), the entire organization becomes the site of training, or in the case of a “moving” simulation, different parts of an organization become the site of training. If the simulation training takes place outside the organization, but uses the equipment and personnel of the organization, it is called “mobile” simulation.

Often simulation personnel that work in a dedicated center may either also conduct simulations “in situ,” “peri-situ,” “mobile,” and “moving patients exercises” or may mentor others who do so. The advantages and disadvantages of different simulation sites are discussed in each respective section and summarized in Table 7.2. Sørensen and associates give an overview of the advantages and disadvantages of different simulation sites in a recent publication in 2017.[199]

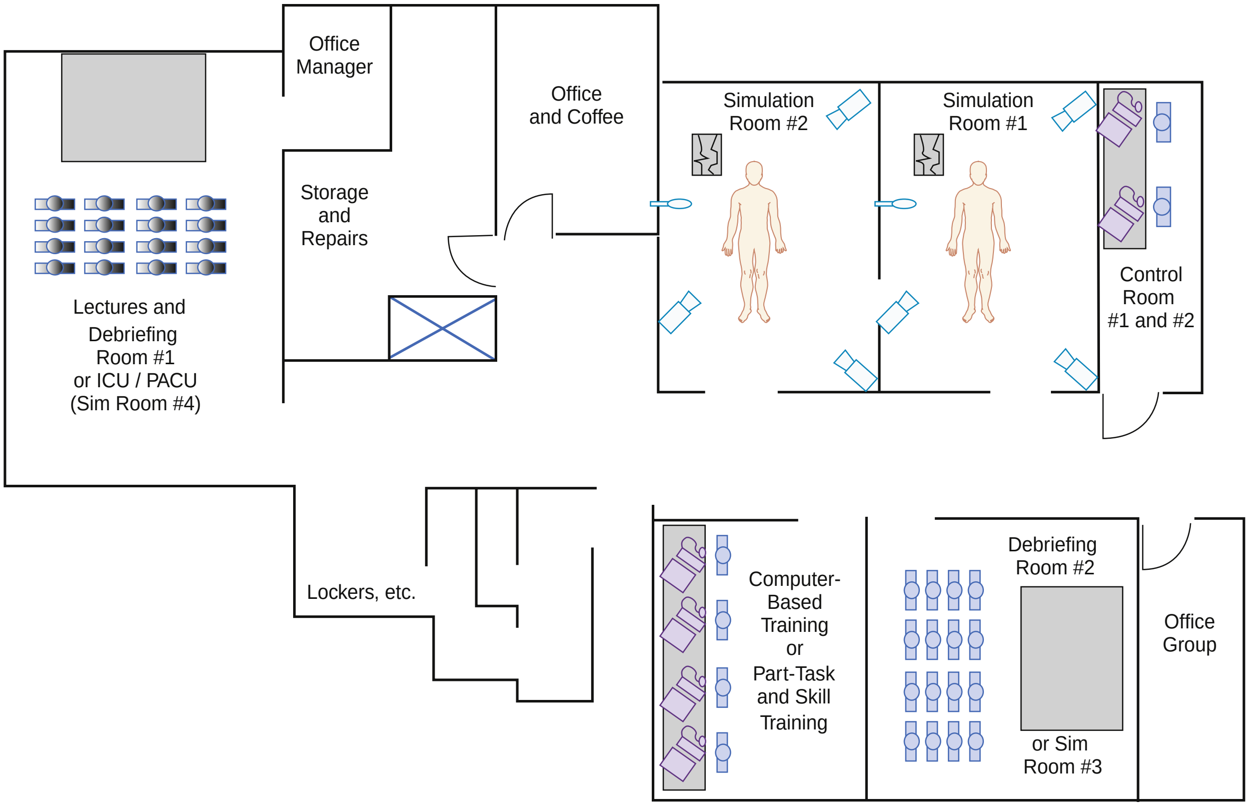

Fig. 7.5 Simulation Center Floor Plan. An intermediate-sized simulation center with four simulation rooms (sim room), a computer-based training room, and several multipurpose rooms, equipped with audio-video patch panels to adjust the room use flexibly to the needs of different training activities (e.g., the large seminar room can be used as a large intensive care unit *[ICU]* or postanesthesia care unit *[PACU]*). (*Figure by M. Rall & E. Stricker, Center for Patient Safety and Simulation [TuPASS], Tübingen, Germany.*)

DEDICATED SIMULATION CENTER

Many institutions have chosen to construct one or more complete simulation centers in which to conduct a variety of education and training sessions. At a few places entire “simulation hospitals” have been created (e.g., Miami, https://simhospital.sonhs.miami.edu/). Some useful websites of simulation centers and other resources are listed at the end of the chapter (Appendix 7.1). The cost structure of a simulation center is a complex issue (see later subchapter). But these programs and their managers in charge have already voted with their feet on the issue of cost versus benefit.

In a dedicated simulation center, one or more simulators may be used, typically in rooms that partially or fully replicate, in a relatively generic fashion, various clinical environments (e.g., operating room, ICU, labor and delivery, emergency department, etc.). Fig. 7.5 and Fig. 7.6 show the floorplan of a medium-sized and a large simulation center. Fig. 7.6 shows the floor plan of the Immersive Learning Center at Stanford University, a pioneering center for health care simulation.

Typically, simulation centers provide a separate control room to allow complex simulations to be presented without an instructor intruding on the simulated case. Fig. 7.7 shows a simulation control room. Many simulation centers have audio-video systems allowing the recording of multiple views during patient simulation. Some centers have computer-based systems to allow annotation of video on the fly and rapid search to the marked portions, but others have found that such mechanisms are not necessary to support debriefing. Dedicated centers typically provide one or more debriefing rooms, often with video replay capability. Ideally a center is located to be easily accessible to a variety of participant populations. Designing, equipping, and overseeing construction of a simulation center may benefit from special knowledge or prior experience.[200,201]

Universities and hospitals or hospital networks are increasingly constructing very large multidisciplinary and multimodal simulation facilities that often still have anesthesiologists in leadership positions. Often, these kind of facilities combine all the types of simulation and immersive learning in one large unit, including actors playing SPs (usually in clinic settings), mannequin-based simulation, part-task and surgical and procedural trainers, wet and dry work (e.g., plaster casting or procedures on food products), and different forms of VR. Sometimes these incorporate facilities for dissection of cadavers or the use of anesthetized animals but often these are in other pre-existing sites. Some institutions have many simulation centers, associated with different learner populations, in different locales, or featuring different kinds of simulation equipment.

Advantages and Disadvantages of Dedicated Simulation Centers. Simulation in a dedicated center facilitates scheduled training and allows the use of complex audiovisual gear and a variety of simulation and clinical equipment, with substantial storage. Devices can be preset, tested, and

ready to go, with briefing and debriefing facilities immediately at hand. In a dedicated center inexpensive discarded, flawed, or outdated clinical equipment and supplies can be safely used. When a center incorporates all modalities of simulation in one place it fosters hybrid techniques, as when an actor playing a standardized patient is combined with a part-task trainer, or when a surgical simulator is combined with a mannequin-based patient simulator.

The main disadvantage of a dedicated center is its cost of construction and outfitting. Moreover, no matter how well equipped it is, it can never replicate the equipment, layout, and clinical processes of any specific clinical workplace. Also, participants know from the very beginning that the activity is a simulation and not the real thing.

TRAINING AND PROBING WHERE CLINICIANS WORK

There are several approaches to conducting simulations in or near actual sites of clinical work. By necessity institutions without a dedicated simulation center must use one of these approaches, but they are useful for many other reasons.

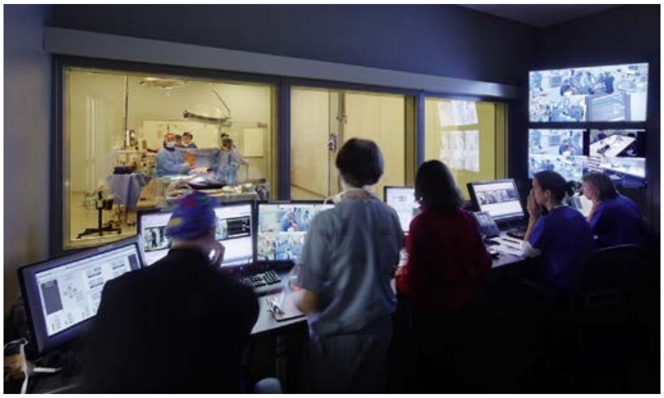

Fig. 7.7 Simulation control room. Through a window wall the simulation control room is separated from the actual simulation room. Several instructors can have a look on the simulation either via the windows, or via one of the several screens that show different views of the simulation room. In front of the instructors the workstation for control of the simulator system itself is placed, including an audio control desk with control of the simulated patient voice, the voice for in-scenario guiding, and several wireless headset channels. (*Photograph provided by D.M. Gab; control room of the Stanford Immersive Learning Center.*)

In Situ Simulation

In situ simulation is conducted in an actual bed/gurney/bay of a real clinical workplace, such as, for example, OR, ICU, trauma room, postanesthesia unit, or ward. ISS training is often used for complex patient simulation scenarios with experienced single-discipline or interprofessional staff. It is typically used for training in order to create high environmental fidelity and/or to probe procedures or the system (see earlier subchapter "Application of Simulation").[4,75,83-87,202] ISS can be a useful training option especially for training in unique workplaces that are difficult to recreate with adequate realism (see later subchapter on simulation realism) in a simulation center or elsewhere, such as a catheterization laboratory, a CT scanner, an ambulance, or an air rescue aircraft (Figs. 7.8 to 7.15).

Rosen and colleagues[203] reviewed the use of in situ simulation in the continuing education for health care professions. They summarized that a positive impact of ISS on learning and organizational performance has been demonstrated in a small number of studies. They also indicated that the evidence surrounding ISS efficacy is still emerging and that existing research is promising.

Most ISS is performed mobile as a temporary setup only for the training sessions. In very few institutions a simulator is permanently installed in a clinical workplace, for example, creating a simulation-specific patient room in the actual ICU.

Advantages and Disadvantages of In Situ Simulation. ISS seems ideal in that it probes and challenges personnel and systems as they actually exist, thus unmasking real issues of patient care. It is available, in principle, to all sites, even those without a dedicated center, and it is conducive to short courses and unannounced mock event drills.

Because it takes place in the actual work unit, it will eliminate travel time to a dedicated center and will put participants at ease. Some substantial disadvantages include potential distractions by ongoing clinical work, lack of privacy, logistics of setup and takedown, reduced availability of AV and simulation equipment, and supply costs (many ISS activities use the unit's real clinical supplies as needed).[204] ISS can be difficult to organize, schedule, and control. The clinical area planned for simulation may not be vacant or may be needed on short notice. Staff members engaged in the simulation are prone to being pulled into clinical duty, and training sessions may be interrupted. Raemer[204] summarized potential risks of ISS and amplified some of the safety hazards of simulation itself including maintaining control of simulated medications and equipment, limiting the use of valuable hospital resources, preventing incorrect learning from simulation shortcuts, and profoundly upsetting patients and their families. In our experience, patients and families are rarely upset and in fact often are pleased to see that such serious training is going on.

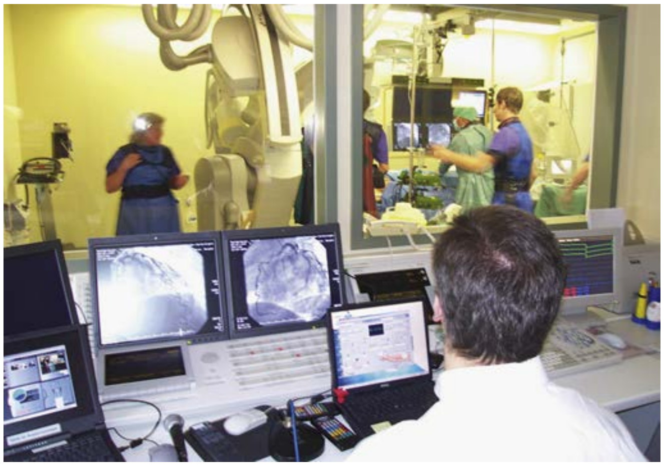

Fig. 7.8 In situ mobile simulation in a catheterization laboratory (cath lab). The simulator is placed on the cath lab table, surrounded by the x-ray equipment, thus complicating treatment of the patient by limiting space. The vital signs monitor provides relevant data to the clinical team. The simulator is controlled from the cath lab control room. Multiple mobile cameras and a scan converter for vital signs provide a live video transmission to a temporary debriefing area for the nonactive part of the training group and allows for crisis resource management–based debriefings. (*Photograph by M. Rall.*)

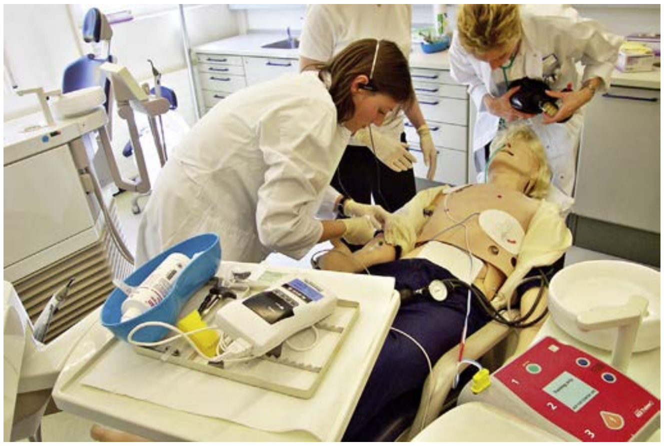

Fig. 7.9 In situ mobile simulation in a dentist chair. The simulator was equipped with artificial teeth gum and a chalk tooth to drill, thereby simulating the dentist's procedures. Then emergencies developed, allowing the team to respond. Training focused on crisis resource management key points and medical aspects including use of an automated external defibrillator. (*Photograph by M. Rall.*)

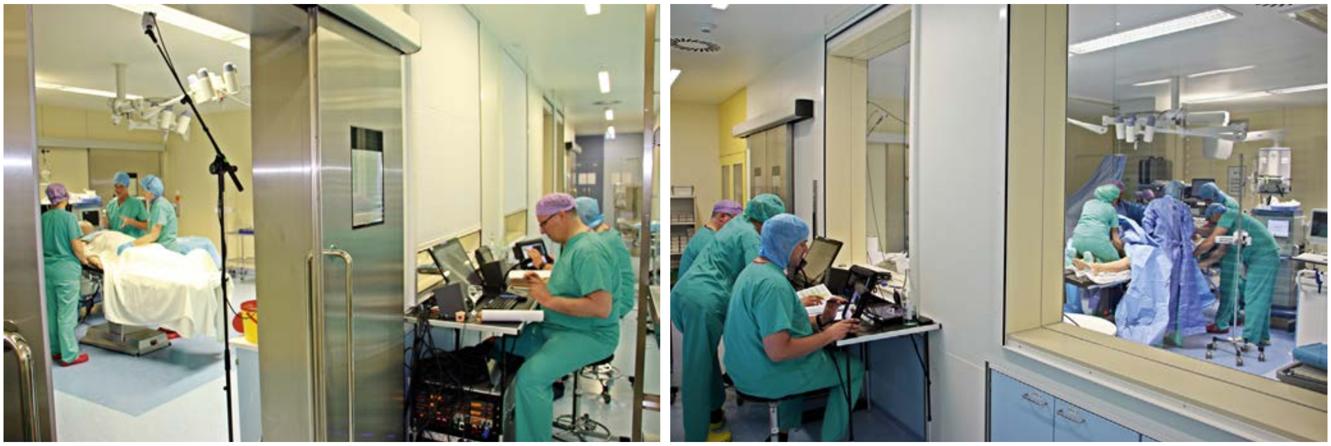

Fig. 7.10 In situ mobile simulation team training in the operating room (OR). The mobile simulation control room is set up outside the OR. The instructors can watch the simulation scenario either indirectly via live video coverage (left photo) or directly via the OR window (right photo). (*Photograph provided by M. Rall, InPASS in situ training in the OR at Scuol Hospital, Switzerland, Chairman: J. Koppenberg.*)

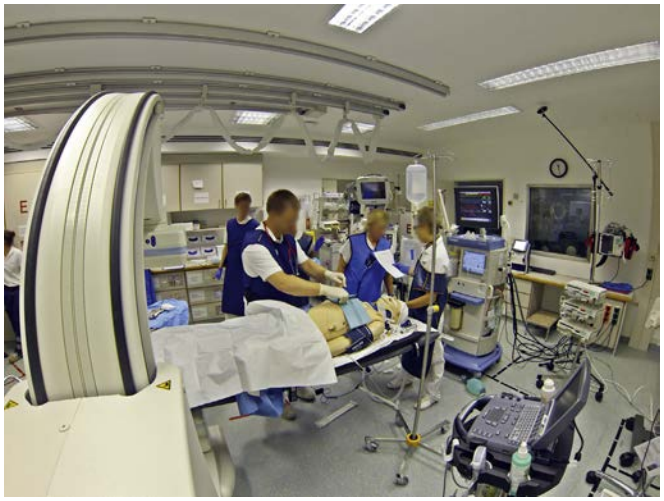

Fig. 7.12 In situ mobile simulation trauma team training at a large trauma center. (*Photo provided by M. Rall.*)

Peri-situ or Off-site Simulation

If simulation is, in principle, worthwhile, then doing simulation anywhere is probably better than not doing it at all. *Peri-situ simulation* (PSS) means simulating in the clinical work unit, but not in an actual patient room/bay/bed—for example in a conference room, or even hallway of the unit. This may be done when an ISS session is planned but there is no actual clinical spot available, or it may be done this way on purpose. PSS has some of the advantages of ISS in terms of locale, systems, and supplies, but it lacks the ideal realism of an actual bedside. When simulation is done outside a clinical unit (say a nonclinical conference room) or in a public area of a hospital it is referred to as *off-site simulation* (OSS).

Sequential Location Simulation

This is sometimes called *moving simulation* and it simulates the patient moving between different sites of care in one scenario, at each stop enacting what might transpire in that location. For example, the patient could be brought to the emergency department by ambulance; assessed and treated; then taken to CT scan, interventional radiology, or OR; and finally transferred to an ICU. Moving simulation may be best accomplished as ISS or PSS, but again, there will be some value to it even if each stop cannot be simulated perfectly. To do it with full veracity requires intensive coordination and complex choreography of simulation equipment and personnel. It is probably only worth it if done occasionally and primarily with a focus on systems probing and improvement. Moving simulations can address different specific issues at each stop, depending on the most important systems probing and learning issues for each.

Advantages and Disadvantages of Moving Simulation. Like all kinds of ISS, moving simulation is a powerful tool to detect latent threats in the system. Apart from a focus on latent threats in certain workspaces, this kind of ISS can detect challenges in the course of transport to those workspaces. As mentioned above, the organizational and technical preparations, the technical challenges, and the movement of the whole simulation gear paired with the clinical staff needed in order to make moving simulations work imply huge effort.

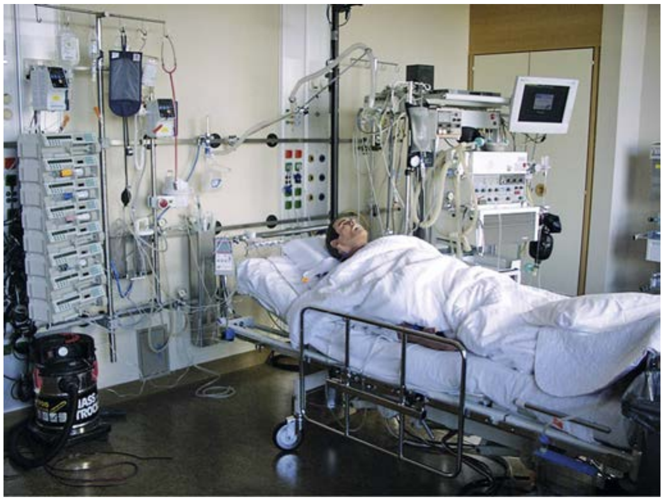

Fig. 7.13 In situ mobile simulation in an intensive care unit (ICU)/ intermediate medical care unit location. The training in clinical areas is especially useful for ICU-like surroundings. Crisis resource management–based trainings showcase these highly complex problems and the interactions needed to coordinate high-performing ICU teams. The training allows for checking the local arrangement of equipment and the readiness to react to certain emergencies. There are already a few examples of permanent in situ simulation facilities in ICUs (see text). (*Photograph by M. Rall.*)

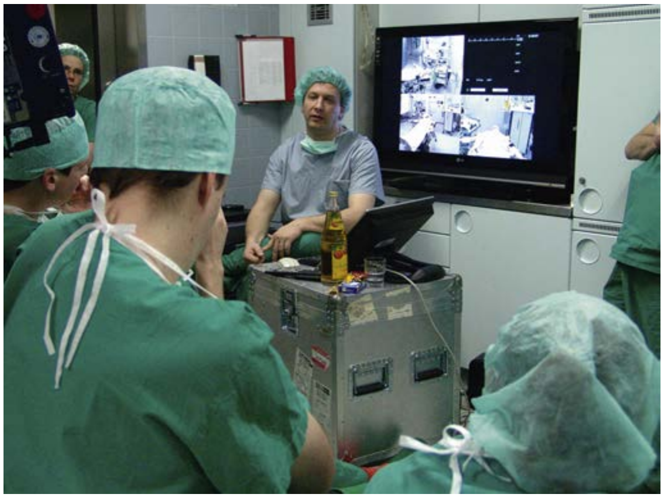

Fig. 7.14 In situ mobile crisis resource management (CRM)–focused simulation team training inside an operating room. This debriefing room is temporarily set up in an induction room. The use of videos for debriefing (here on a 42-inch flat panel placed over the basin) is feasible even in this setting. Training inside a hospital often includes training actual teams with the same setup, if possible conducting training for a large proportion of the relevant personnel. "En-bloc" training sessions may have a greater impact and longer-lasting effects of the lessons learned, including CRM behaviors. (*Photograph by team TuPASS [Center for Patient Safety and Simulation, University Hospital, Tübingen, Germany], who performed a full team training of the anesthesia department at Steinenberg Medical Center, Reutlingen, Germany.*)

MOBILE SIMULATION: "HAVE SIMULATOR, WILL TRAVEL"

Mobile simulation means that the simulator and the audiovisual gear are transported outside the originating institution for purposes of a simulation event. This makes simulation activities an option for clinical sites that lack a dedicated simulation center or the expertise to do ISS/PSS in their own institution.

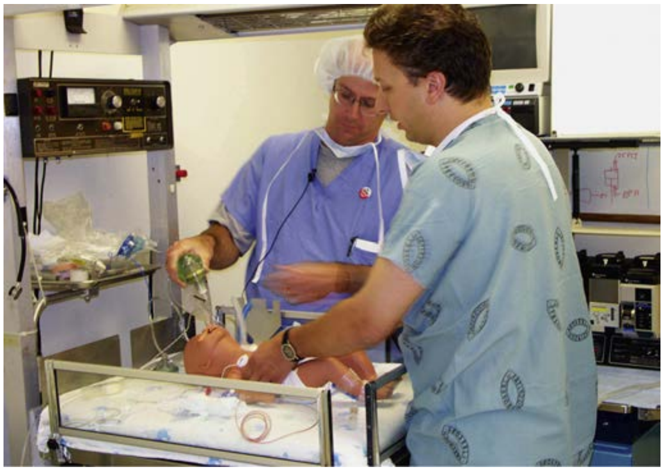

Fig. 7.15 Neonatal crisis resource management and resuscitation training at a neonatal emergency workplace. The experienced instructor (on the right side of the infant) is a confederate acting as part as the team, whereas others in the control room preside over simulation. (*Photograph taken at Stanford Simulation Center, Stanford University, Palo Alto, California; provided by M. Rall.*)

Mobile simulation can be conducted in clinical settings or in conference rooms, or even hotel meeting rooms. Mobile simulation can be provided by staff from simulation centers that have mobile simulator and audiovisual equipment and are equipped to travel with it. In some places there are small simulation centers built into a truck or bus.

Advantages and Disadvantages of Mobile Simulation. For clients who use mobile simulation, the construct of mobile simulation for sure is a great way to know the promise of simulation training and system probing without extra time and money for staff travelling. At the same time, mobile simulation offers the advantage of external peer feedback. This way normalizations of deviance (see Chapter 6) and pitfalls that are not noticed by internal personnel anymore can be detected by external instructors. Organizations that offer mobile simulation show a greater flexibility for training opportunities. Such organizations can not only offer training at nearly any workspace in their own organization, but also offer simulation to other organizations. This way, the organization's own simulation activities might be funded and vacant equipment and personnel capacities used.

Simulation Team Training Participants: Who Should Be Trained and in What Composition?

Each discipline in health care can be considered a *crew* containing one or more individuals. Several crews may work together closely as a *team*. The operating room team, for example, consists of an anesthesia crew, a surgery crew, and a nursing crew (and crews of technicians and support personnel). The members within a crew are likely to be more familiar with each other than with members of other crews. Such mutual professional (and private) "knowing about each other"—perhaps by enhancing their shared mental model—could be an important influence on their performance.[205]

Many simulation applications are targeted at individuals. These may be especially useful for teaching knowledge and basic skills or for practice on specific psychomotor tasks. As in other high-reliability industries (including anesthesiology, see chapter 6), individual skill is a fundamental building block, but empiric findings show that individual performance is not sufficient to achieve optimal overall performance, and to achieve optimal safety.[206] Performance and safety unfold in the interplay between people and in their interaction with each other, equipment, and organizational structures and processes. That is the reason why in high-reliability organizations a considerable emphasis is applied at higher organizational levels, in various forms of teamwork and communication training, and interpersonal relations. This approach is often summarized under the rubric of *crisis resource management* (see Chapter 6 and later section).[24,207,208] The importance of teamwork and team training is widely accepted in health care and anesthesia,[33,209-216] although team training is still not widely implemented. The prerequisites for effective teamwork (e.g., team leadership, mutual performance monitoring, back-up and speak-up behavior, adaptability and team orientation, the concept of team cognition, etc.) are discussed in Chapter 6. One of the special features of health care teams that poses several challenges is the frequently changing composition of teams with changing crews. Within a discipline, crew membership may fluctuate. For example, in anesthesia or the resuscitation team. Those teams or crews are also referred to as "action teams" (see Chapter 6).

When simulation is intended to go beyond specific medical and technical skills for individuals (as, for example, in CRM-oriented patient simulation) and to involve non-technical skills and teamwork, one can distinguish between single-discipline and multidiscipline approaches. CRM-based "team training" may be addressed first to *crews* (known as *single-discipline teams*), and then to *teams* (known as *multidiscipline teams*).[217] Commonly, in a broader sense and used this way in this chapter, the term "team training" refers to both single-discipline as well as multidiscipline training. For both approaches the best way to train and transfer learning for everyday instances at work is to arrange the training (1) interprofessional (doctors, nurses, allied health personnel, etc.) and (2) in realistic crew/team compositions and roles in regard to the learning objective ("train as you work"—see patient simulation action box below).

PATIENT SIMULATION ACTION BOX

"Train as you work." When conducting patient simulation training with more experienced personnel—beyond "early learners"—those who work together should train together when possible. Although built on a foundation of previous experience and crew-specific training, working together in simulation will hone the skills of coordinating tasks, goals, and strategies in the overall treatment of the patient.

Furthermore, teams exist in actual *work units* in an organization (e.g., a specific ICU), each of which can be its own target for training, and in *organizations* as a whole (e.g., entire hospitals or networks). Each unit can have specific characteristics, culture, etc., that will influence how receptive participants are for training and how easily they can apply in the clinical setting what they learned during simulation. Growing interest and experience have been shown in applying simulation to nonclinical personnel and work units in health care organizations (e.g., to managers, executives, informal leaders).[73,74]

Addressing teamwork in the single-discipline approach in contrast to the multidiscipline approach has advantages and disadvantages.[155] For maximal benefit, these approaches are used in a complementary fashion.

TRAINING INDIVIDUALS

Simulation-based training of individual skills can be used to educate learners (Miller learning pyramid "knows," "knows how," see Fig. 7.4), to promote psychomotor skills ("knows how," "shows how"), and to help integrate different kinds of skills into an effective whole. Usually, early learners need to start somewhere, as do experienced people trying to learn completely new skills or procedures. Whereas screen-based simulators can be used for educational purposes and the acquisition of basic procedural knowledge, part-task trainers promote psychomotor skills, and mannequin-based simulation allows training to bring different concepts together. When mannequin-based simulation is used for the training of individuals (who still perform as a crew!), the focus of patient simulation training lies either (1) on training an individual's clinical skills, for example following a treatment algorithm; or (2) on training non-technical skills such as leadership, communication, task management, etc.; or (3) both.

TRAINING CREWS: INTERPROFESSIONAL SINGLE-DISCIPLINE TEAM TRAINING

Training for crews (e.g., anesthesiologists) involves simulation scenarios, in which all participants are from a single discipline and in which the scenarios are highly relevant to the crew (both in regard to clinical and non-technical skills). The other team members' roles (i.e., surgeons, etc.) are either played by instructor personnel or clinically savvy actors; less critical team roles may be played by participants or, when necessary, not present at all. In this approach the interaction with specific types of behaviors by other crew or team members can be addressed by an instructor or an actor assuming that role as a confederate. These roles can be designed such that participants can be exposed to different kinds of challenges systematically.

This approach allows tailoring simulations to challenge skills, knowledge, and situations specific to the discipline, including material that may be of little relevance to other members of the team and in the context of a wide variety of clinical situations (e.g., cardiac, orthopedic, or general surgery; labor and delivery; intensive care). Single-discipline training can emphasize generic skills of dynamic decision making, resource management, leadership, and teamwork applicable to any challenging clinical situation that is relevant to the particular discipline.

The single-discipline approach may be of particular relevance and value for professionals who work in many different settings and who do not work in permanent crews or teams ("action teams," such as in anesthesia, see Chapter 6), and who therefore must acquire generic teamwork and communication skills that can be used with all co-workers. For dedicated center simulations, single-discipline sessions are simpler logistically because only one discipline needs to be present, rather than scheduling someone from each of the disciplines.

TRAINING TEAMS: INTERPROFESSIONAL MULTIDISCIPLINE TEAM TRAINING

In health care, interdisciplinary teams are becoming ubiquitous. At the same time, experts from each discipline do not necessarily combine to make an expert team.[218] The complementary approach is to conduct *multidiscipline team training* (also called *combined team training* or *interprofessional training [IPE]).* Here, the crews of different disciplines who might work together undergo training together, each acting in their own usual roles, and scenarios designed to challenge all of the disciplines. Multidiscipline team training allows for more natural team interactions and reinforces understanding across the disciplines. Successful examples of such undertakings have been reported in many fields where anesthesia professionals are involved, including the OR,[159,219] obstetrics[220-222] (combining obstetrics, anesthesia, nursing, and neonatology and pediatrics), intensive care (combining physicians from multiple disciplines with nursing, respiratory therapy, and pharmacy),[223] emergency department,[224,225] and trauma management.[30,31,90,226,227]

Depending on the training location (see earlier subchapter), the scheduling of the team training poses several challenges. Multidiscipline training, for example, can be difficult to schedule in a dedicated simulation center. Ideally, the sessions will have instructors from several disciplines especially to handle debriefing. Multidiscipline trainings are typically easier to organize as in situ trainings (see earlier subchapter), or as announced or unannounced “mock events” (see next subchapter) that activate the actual designated team (e.g., ward or unit team, rapid response team, or code team). In the latter situation, the team does not know it is a simulation until they arrive at the scene.

CROSS TRAINING: CHANGING ROLES

The course director of a simulation activity can choose whether to have all participants act in their own regular role, or to assume a different role. Each has its advantages. The philosophy of “train as you work and work as you train” would usually put everyone in their usual role,[82] but cross-training can provide an understanding of and sensitivity to the tasks, decision making, challenges, and responsibilities of another profession or discipline. Study results indicate that cross-training is an important determinant of effective teamwork process, communication, and performance,[228] enhanced shared team-interaction and mental models,[229] and helps to maintain team communication when faced with increased task demands.[230]

PATIENT SIMULATION ACTION BOX

If a cross-training scenario is conducted it is advisable to brief personnel to represent the other professional role in a rational manner without playing out particular personality quirks or go “over the top.” The debriefing should emphasize discussion on what individuals can learn from “walking in someone else’s shoes.” It would be foolish, for example, to debrief anesthesia professionals on their surgical skills or behavior as a surgeon. Acting out may be fun for play but it is disrespectful to others, and wastes valuable simulation time.

EN-BLOC TRAINING: AVOIDING SUB-THRESHOLD TRAINING EFFECTS

If patient simulation is used as an intervention to promote a patient safety initiative, for example the introduction of crisis resource management (see Chapter 6) to crews or teams, or the implementation of a new checklist, algorithm, etc., the organization/curriculum designer may arrange that all crew and team members are trained within a short period of time (i.e. several days or weeks). This would provide a more concentrated and uniform result. On the other hand, this may not be possible logistically or politically within the institution, and may or may not be worth the “political capital” to make it happen. As there are no data to demonstrate the strength of the en-bloc effect, it is necessary to gauge under what circumstances it is worth the effort.

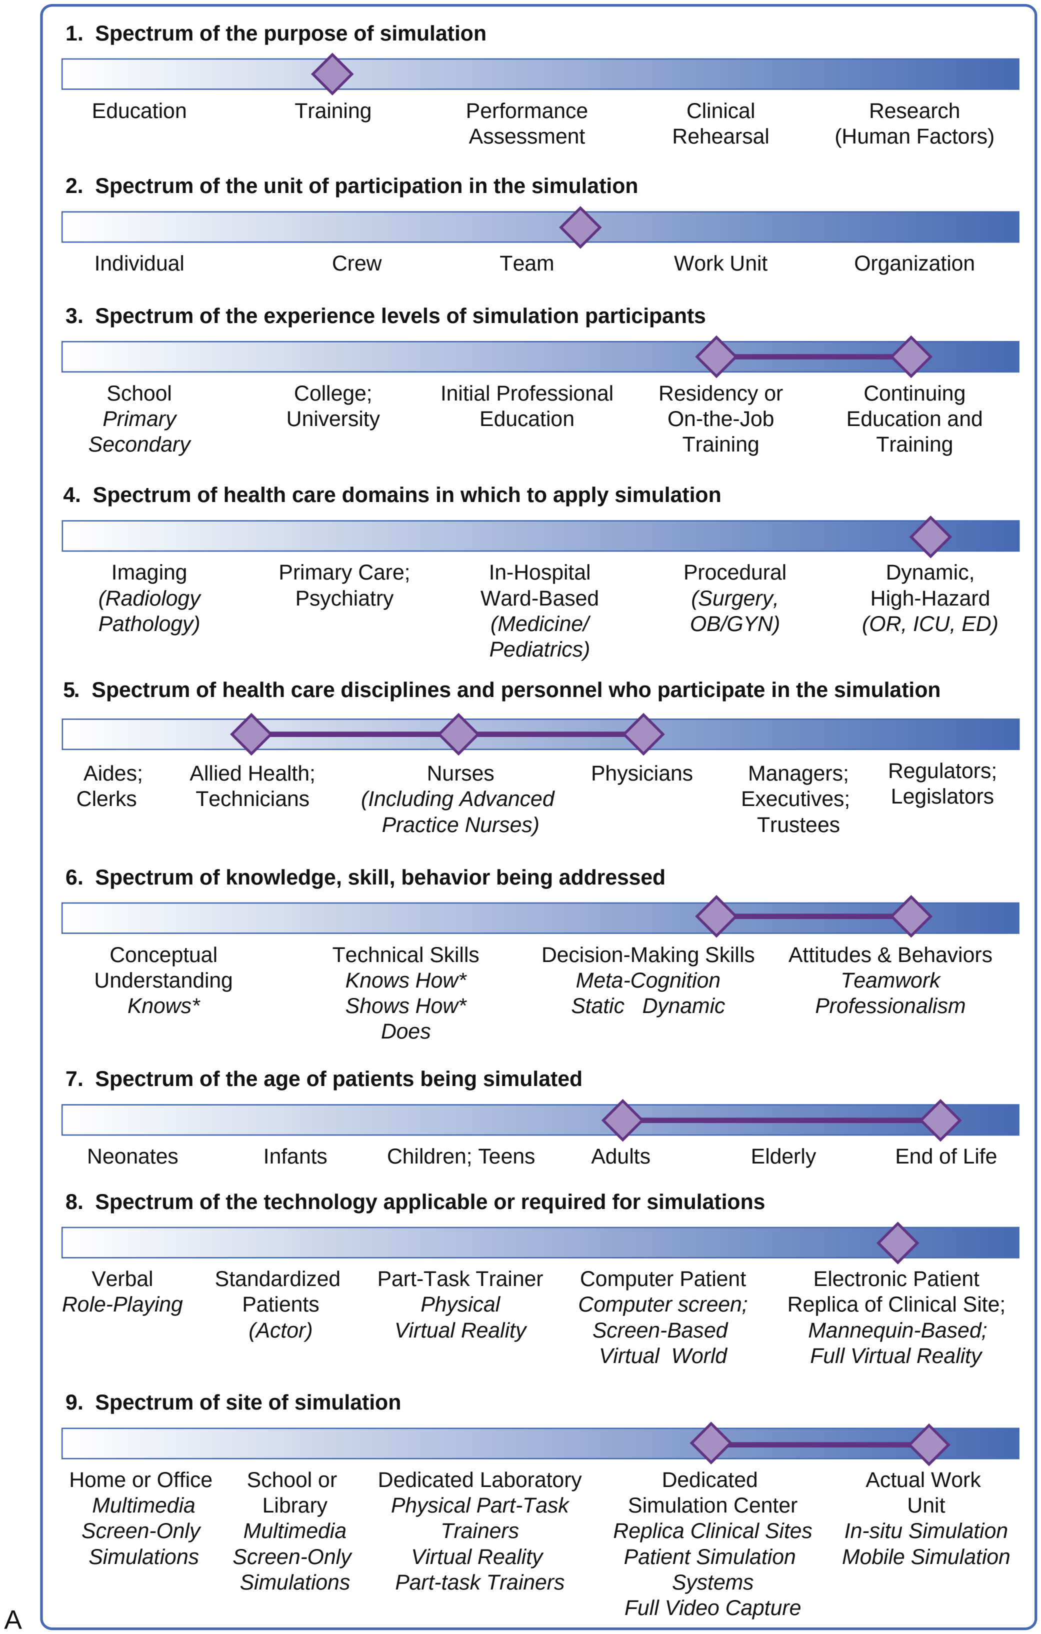
Patient Simulation Timing: Announced in Advance Versus Unannounced in Advance

Regardless of site, simulations can be conducted as pre-scheduled exercises either for personnel in their regular-duty roles or for personnel on off-duty or education days. Typically, unannounced mock events (announced as if the real thing) would be implemented in a department after making potential participants aware of this possibility on a general level. Again, scheduled and unscheduled ISSs are complementary approaches, each with its own pros and cons. An obvious challenge is that it takes participants away from their actual patient care activities so that ground rules need to be established concerning when and how to abort the exercise when necessary. On the other hand, when done only occasionally and with appropriate safeguards, the clinical system needs to probe its ability to ensure good patient care when an emergency team is called to an event. In summary, the technique has high potential for organizational learning when done carefully.

A number of recent publications discuss the advantages and disadvantages of unannounced mock events as well as issues concerning the implementation of such programs.[199,231-233]

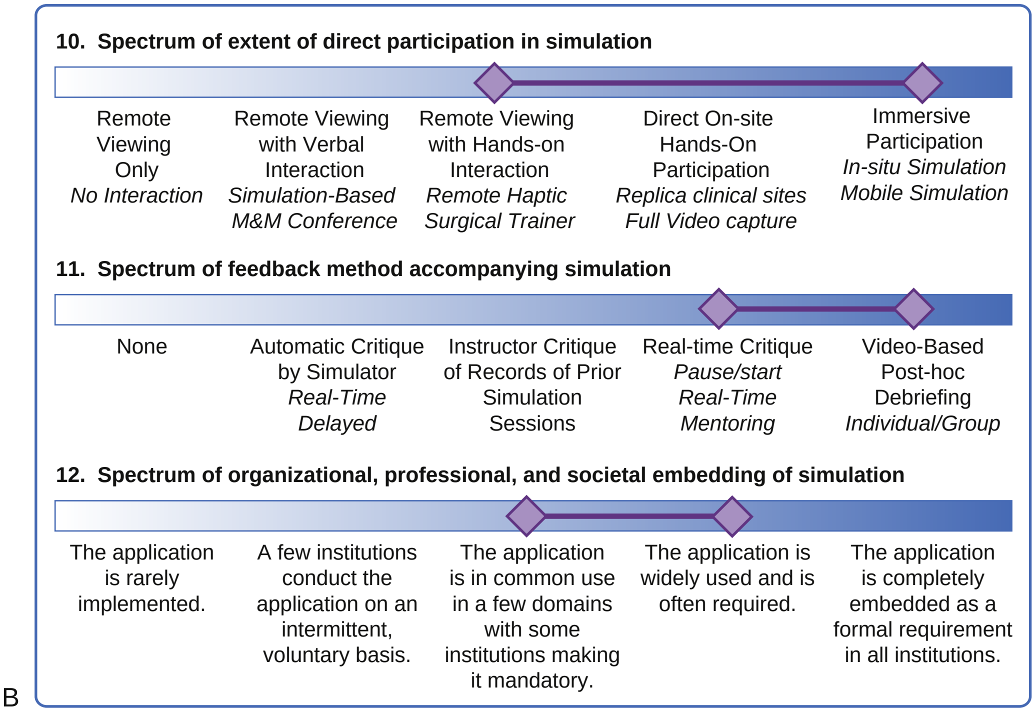
Scopes of Simulation in Health Care: The 12 Dimensions of Simulation

Many different aspects and variations of simulation have been presented so far; they represent examples of combinations of choices from 12 (originally 11[171]) different dimensions of the simulation universe. Each dimension has a variety of choices—a spectrum—to choose from (Fig. 7.16).



1. Spectrum of the purpose of simulation
Education
Training
Performance Assessment
Clinical Rehearsal
Research (Human Factors)
2. Spectrum of the unit of participation in the simulation
Individual
Crew
Team
Work Unit
Organization
3. Spectrum of the experience levels of simulation participants
School *Primary* *Secondary*
College; University
Initial Professional Education
Residency or On-the-Job Training
Continuing Education and Training
4. Spectrum of health care domains in which to apply simulation
Imaging *(Radiology Pathology)*
Primary Care; Psychiatry
In-Hospital Ward-Based *(Medicine/ Pediatrics)*
Procedural *(Surgery, OB/GYN)*
Dynamic, High-Hazard *(OR, ICU, ED)*
5. Spectrum of health care disciplines and personnel who participate in the simulation
Aides; Clerks
Allied Health; Technicians
Nurses *(Including Advanced Practice Nurses)*
Physicians
Managers; Executives; Trustees
Regulators; Legislators
6. Spectrum of knowledge, skill, behavior being addressed
Conceptual Understanding *Knows**
Technical Skills *Knows How** *Shows How** *Does*
Decision-Making Skills *Meta-Cognition* *Static Dynamic*
Attitudes & Behaviors *Teamwork* *Professionalism*
7. Spectrum of the age of patients being simulated
Neonates
Infants
Children; Teens
Adults
Elderly
End of Life
8. Spectrum of the technology applicable or required for simulations
Verbal *Role-Playing*
Standardized Patients *(Actor)*
Part-Task Trainer *Physical* *Virtual Reality*
Computer Patient *Computer screen;* *Screen-Based* *Virtual World*
Electronic Patient Replica of Clinical Site; *Mannequin-Based;* *Full Virtual Reality*
9. Spectrum of site of simulation
Home or Office *Multimedia* *Screen-Only* *Simulations*
School or Library *Multimedia* *Screen-Only* *Simulations*
Dedicated Laboratory *Physical Part-Task* *Trainers* *Virtual Reality* *Part-task Trainers*
Dedicated Simulation Center *Replica Clinical Sites* *Patient Simulation* *Systems* *Full Video Capture*
Actual Work Unit *In-situ Simulation* *Mobile Simulation*
A

Fig. 7.16 The 12 dimensions of simulation applications. (A) Dimensions 1-9. *These terms are used according to Miller's pyramid of learning.



10. Spectrum of extent of direct participation in simulation
Remote Viewing Only *No Interaction*
Remote Viewing with Verbal Interaction *Simulation-Based M&M Conference*
Remote Viewing with Hands-on Interaction *Remote Haptic Surgical Trainer*
Direct On-site Hands-On Participation *Replica clinical sites* *Full Video capture*
Immersive Participation *In-situ Simulation* *Mobile Simulation*
11. Spectrum of feedback method accompanying simulation
None
Automatic Critique by Simulator *Real-Time* *Delayed*
Instructor Critique of Records of Prior Simulation Sessions
Real-time Critique *Pause/start* *Real-Time* *Mentoring*
Video-Based Post-hoc Debriefing *Individual/Group*
12. Spectrum of organizational, professional, and societal embedding of simulation
The application is rarely implemented.
A few institutions conduct the application on an intermittent, voluntary basis.
The application is in common use in a few domains with some institutions making it mandatory.
The application is widely used and is often required.
The application is completely embedded as a formal requirement in all institutions.
B

Fig. 7.16, cont'd. (B) Dimensions 10-12. Any particular application can be represented as a point or range on each spectrum (shown by *diamonds*). This figure illustrates a specific application: multidisciplinary crisis resource management (CRM)-oriented decision making and teamwork training for adult intensive care unit *(ICU)* personnel. *ED,* Emergency department; *M&M,* morbidity and mortality; *OB/GYN,* obstetrics and gynecology; *OR,* operating room.

Any particular simulation activity can be classified by delineating one or more characteristics in each of the 12 dimensions. The different attributes can be combined as needed to achieve the pursued objectives. Clearly, some combinations are useless or irrelevant, some are similar to each other, and others are redundant, but the total number of unique combinations across all dimensions is still very large and only some combinations have been implemented. Dimensions of particular relevance are the goals and purposes of the simulation, the target population, the modalities of simulation, and the pedagogical approach that is used.

The content of many dimensions has been addressed in detail in the earlier parts of the chapter. Therefore, for the sake of completeness, only a short description of the dimensions is given here and the reader is referred back to each section for more information. Those who seek a detailed description of the different dimensions are referred to other literature where the model is described as a whole in detail.[75,234]

Dimension 1: Purpose and Aims of the Simulation Activity. The most obvious applications of simulation have been described in the subchapter "Application of Simulators in Anesthesia and Health Care." For more detailed information the reader is referred back to this section. To summarize the main purposes shortly, they are (1) education, (2) training including clinical rehearsal, (3) performance assessment, (4) research about simulation, and (5) research with simulation, including (5a) testing of procedures, (5b) testing of equipment, and (5c) system probing.

Dimension 2: Unit of Participation in the Simulation. The units of participation have been described in the subchapter on the classification of simulation teams. For more detailed information the reader is referred back to this section.

Dimension 3: Experience Level of Simulation Participants. Simulation can be applied along the entire continuum of education of clinical personnel and the public at large. For more information see earlier subchapter on the use of simulation in education and training. As mentioned earlier, simulation training is applicable to health care providers with a range of experience, including experts,[2,50] novices and advanced residents,[2,90,178,235,236] medical/nursing/other healthcare profession students,[51,52,53-57] and even children.[58-61]

Dimension 4: Healthcare Domain in Which Simulation is Applied. Simulation techniques can be applied across nearly all health care domains.[18] A summary of the different domains was given in the earlier subchapter on "Use of simulation."

Dimension 5: Healthcare Disciplines of Personnel Participating in the Simulation. Simulation is applicable to a wide variety of professionals in health care, not only to physicians. In anesthesiology, simulation has been applied to novices and experienced trainees, board certified anesthesiologists, CRNAs, and anesthesia technicians. Simulation is not limited to clinical personnel. It may be directed at managers, executives, hospital trustees, regulators, and legislators.[73,74]

Dimension 6: Type of Knowledge, Skill, Attitudes, or Behavior Addressed in Simulation. Different types of competences can be addressed with simulation: knowledge, skill, attitudes, behavior. Based on the Miller pyramid (see corresponding subchapter), competences can be classified with regard to their level of appearance to "knows," "knows how," "shows how," and "does." Apart from the competences described by Miller,[197] Gaba[234] added cognitive skills such as decision-making processes, attitudes, and behaviors to the competences that can be addressed with the spectrum.

Dimension 7: Age of the Patient Being Simulated. Simulation is applicable to nearly every type and age of patient. Fully interactive neonatal and pediatric patient simulators are available. Simulation can address aspects of end-of-life issues for every age.

Dimension 8: Technology Applicable or Required For Simulations. To accomplish the different simulation goals listed in dimensions 1, 3, 4, 5, 6, and 7 various simulation technologies—including no technology—are relevant for simulation. An overview is given in the earlier subchapters "History and Development of Simulators," "Fidelity and Classification of Simulators," and "So many simulators and simulation options: which one to use…?".

Dimension 9: Site of Simulation Participation. The different sites of simulation have been described in detail in the correspondent subchapter. Video conferencing and advanced networking may allow even advanced types of simulation to be conducted remotely (see dimension 10).

Dimension 10: Extent of Direct Participation in Simulation. Not all learning requires direct participation. Some learning can occur merely by viewing a simulation involving others because the viewer can readily imagine being in the shoes of the participants.[237] A further step is to involve remote viewers with interaction in the simulation itself or verbal interaction in debriefings about what transpired. Several centers have been using videoconferencing to conduct simulation-based exercises, including morbidity and mortality conferences. Because the simulator can be paused, restarted, or otherwise controlled, the remote audience can readily obtain more information from the on-site participants, debate the proper course of action, and discuss with those in the simulator how best to proceed. Further steps of participation are personal involvement ("hands-on") either in a replicated clinical site or immersive personal participation in an in situ simulation.

Dimension 11: Feedback Method Accompanying Simulation. One can learn a great deal just from simulation experiences themselves, without any additional feedback.[238] For many simulations, specific feedback is provided to maximize learning. On-screen-based simulators or VR systems, as well as the simulator (part-task trainer or mannequin) itself, may provide feedback about the participant's actions or decisions, particularly for manual tasks for which clear metrics of performance are readily delineated. More commonly, human instructors provide feedback. This can be as simple as having the instructor review records of previous sessions that the learner has completed alone. For many target populations and applications, an instructor provides real-time guidance and real-time feedback to participants while the simulation is ongoing. The possibility to start, pause, and restart the simulation is valuable in this respect. Alternatively, brief post-hoc feedback is given by the instructor at the end of the simulation. For the most complex uses of simulation, especially when training experienced personnel, the typical form of feedback is provided by an instructor and is included in a detailed post-simulation debriefing session.[105,107,112,113,238] More discussion of debriefing is given later in the subchapter on "Debriefing."

Dimension 12: Embedding of Simulation in Relevant Organizational, Professional, and Societal Contexts. The final important dimension is how the simulation application is embedded into an overall context.[159] Being highly embedded may mean that the simulation is a formal requirement of the institution or is mandated by the governmental regulator. Another aspect of embedding may be that—for early learners—the initial (steep) part of the learning curve is required to occur in a simulation training before the learners are allowed to work on real patients under supervision. In addition, complete embedding of simulation into the workplace means that simulation training is a normal part of the work schedule, rather than being an add-on activity attended in the spare time of clinicians.

Crisis Resource Management (ACRM; CRM): Part of Modern Patient Simulation Team Training

In the last subchapters, the benefits and the effectiveness of simulation-based education were highlighted and its ecologic validity was considered. This subsequent section now explores the idea that simulation-based education for a variety of simulation curricula, especially for team training, needs to take into account not only medical and technical skills, but also what is called anesthesia crisis resource management (ACRM), also referred to as crisis resource management (CRM). For detailed information on CRM see Chapter 6.

THE ROOTS OF ANESTHESIA CRISIS RESOURCE MANAGEMENT TRAINING

In 1989, based on earlier work, Cooper,[239,240] Howard et al.,[181] and Gaba[241,242] of the VA-Stanford and their colleagues identified gaps in the training of anesthesiologists regarding several critical aspects of decision making and crisis management that were not systematically taught during standard residency or postgraduate education. These gaps were inadequate learning and skills of (1) precompiled plans for dealing with perioperative events; (2) metacognition and allocation of attention; and (3) resource management behavior, including leadership, communication, workload management, monitoring, and cross-checking of all available information.

Historically, it had been assumed that anesthesiologists would acquire these plans and non-technical skills (see Chapter 6) by osmosis, solely by experience and by observing role models who had these qualities, rather than specific education and training about them. But similar to aviation, medicine had to learn that those kind of (non-technical) skills were not acquired unless specifically taught. For flight crews, CRM training was originally created to address these issues. Especially for anesthesia, but for other health care domains as well, the VA-Stanford group modeled their training after aviation CRM and named it ACRM.[181] For a broader use in health care, oftentimes ACRM is also referred to solely as CRM. The ACRM approach has been highly influential. ACRM curricula and ACRM-like curricula are taught at simulation centers around the world, not only in anesthesia, but in many other domains of health care, including ICU, emergency medicine, labor and delivery, trauma, and field responders.[3,93,222,243-247]. Fig. 7.17 shows a typical CRM crew training scenario.

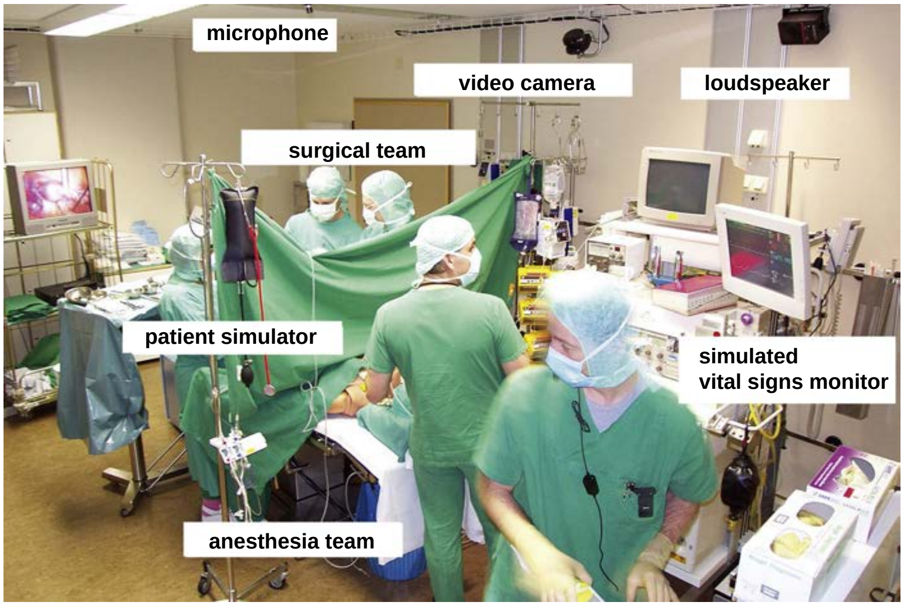


Fig. 7.17 Crisis resource management training scenario during crew training. The surgical team is performing a complicated endoscopic surgical procedure replayed on screen. The anesthesia team must solve a clinical problem and coordinate with the surgical team. Video cameras, microphones, and loudspeakers provide the necessary connectivity and later debriefing tools. (*Photograph taken by M. Rall at the Center for Patient Safety and Simulation, University Hospital, Tübingen, Germany.*)

ANESTHESIA CRISIS RESOURCE MANAGEMENT CURRICULA

A working group of the original ACRM centers (VA-Stanford, Boston CMS, Toronto Sunnybrook) promulgated a set of criteria to be met by a curriculum to be called either ACRM or ACRM-like. Box 7.3 presents an excerpt of the criteria.

Among others, these criteria delineate:

1. To target the above mentioned identified gaps in training, approximately 50% of the emphasis of ACRM is on the medical and technical management of specific high-risk perioperative situations, and about 50% is on generic principles of crisis management that apply to nearly every complex patient care situation. The key teaching points of ACRM are shown in Box 7.4. These points are emphasized during the ACRM simulation course, and their occurrence or omission is highlighted during the debriefing sessions.
2. Special training is needed for instructors in ACRM-like curricula. The authors' experience suggests that the most difficult aspect of ACRM instructing is debriefing, and new instructors require a significant period of experience, preferably under supervision by more senior instructors, before being ready to be fully independent instructors. Several groups working separately or collectively have developed comprehensive training programs on simulation instruction, including substantial modules on debriefing and scenario design (see later subchapter on instructor qualification).
3. ACRM-like curricula employ a variety of teaching modalities to achieve these goals, including the following:
   - Comprehensive textbook on anesthesia crisis management: *Crisis Management in Anesthesiology (now in an expanded second edition)*.[24] This book includes didactic material on ACRM principles and a comprehensive catalog of critical incidents in anesthesia that provides guidelines for preventing, recognizing, and managing 99 perioperative situations in a uniform format. The catalog section of the text is intended to provide study material to increase anesthesiologists' stock of precompiled response plans to common and uncommon situations. This textbook has been translated into Japanese, German (first edition), Spanish, and Portuguese (second edition).
   - Brief presentation and discussion reviewing the principles of CRM and patient safety.
   - Use of trigger videos meant to initiate discussion, sometimes from a non-health care setting (e.g., commercial aviation, British warship during the Napoleonic wars).
   - Group exercises analyzing a patient care event, presented as: (i) an actual patient care event captured on video or a reconstruction thereof; (ii) a video of a presentation as if from a morbidity and mortality conference; or (iii) a written report of the event.
   - The core of simulation activities in ACRM-like curricula will be several hours of different, complex, multifaceted, realistic simulation scenarios in which participants rotate through different roles, including for example primary anesthesiologist, first responder (called cold, with no knowledge of the situation), and scrub tech. Other instructors or actors play the roles of surgeons, nurses, and technicians as in a real perioperative setting. Each situation is followed by a detailed debriefing (see later in discussion on "Debriefing").

Several publications have detailed the response of participants with varying levels of experience to ACRM training or its equivalent.[181,248-250] Participants have

BOX 7.3 Characteristics of Anesthesia Crisis Resource Management-like Simulation Training

Objectives

- Learn generic principles of complex problem solving, decision making, resource management, and teamwork behavior.
- Improve participants' medical and technical, cognitive, and social skills in the recognition and treatment of realistic, complex medical situations.
- Enhance capacity for reflection, self-discovery, and teamwork and for building a personalized tool kit of attitudes, behaviors, and skills.

Aim

- Prevent, ameliorate, and resolve critical incidents.

Course Characteristics

- A realistic simulation environment replicates a relevant work setting (or an actual patient care setting with in situ simulation).
- Personnel will represent those persons found in the typical work environment of the participant, including nurses, surgeons, and technicians.
- The bulk of the training course consists of realistic simulations followed by detailed debriefings.
- Primary participants can request and receive help from other participants.
- Participants may rotate among various roles during different scenarios to gain fresh perspectives.
- Simulation scenarios may be supplemented by additional modalities, including activities such as assigned readings, didactic presentations, analysis of videotapes, role playing, or group discussions.
- Training involves significant time (>4 h, typically ≥8 h) and is conducted with a small group of participants.

Content Characteristics

- Scenarios require participants to engage in appropriate professional interactions.
- At least 50% of the emphasis of the course is on crisis resource management behavior (nontechnical skills) rather than medical or technical issues (non-technical skills are discussed in Chapter 6).
- Observation only is not equivalent to actual participation in one or more scenarios.

Faculty Characteristics

- Training is intense and entails a high level of involvement of faculty with the participants and a low participant-to-faculty ratio.
- Faculty members, especially those leading debriefing, have special training or experience in conducting crisis resource management–oriented training.

Debriefing Characteristics

- Debriefings are performed with the whole group of participants together and use (as appropriate) audio-video recordings of the simulation sessions.
- Debriefings emphasize constructive critique and analysis in which the participants are given the greatest opportunity possible to speak and to critique and to learn from each other.

BOX 7.4 Key Points in Anesthesia Crisis Resource Management

A detailed explanation of the crisis resource management key points is given in *Chapter 6*. The key points are derived from the publication of Rall and Gaba in the sixth edition of Miller's Anesthesia[367] and presented here in their updated, current version.

1. Know the environment.
2. Anticipate and plan.
3. Call for help early.
4. Establish leadership and followership with appropriate assertiveness.
5. Distribute the workload. Use 10 s for 10 min concept.
6. Mobilize all available resources.
7. Communicate effectively—speak up.
8. Use all available information.
9. Prevent and manage fixation errors.
10. Cross and double check. Never assume anything.
11. Use cognitive aids.
12. Reevaluate repeatedly. Apply 10 s for 10 min concept.
13. Use good teamwork. Coordinate with and support others.
14. Allocate attention wisely.
15. Set priorities dynamically.

been extremely positive about their experience in the ACRM course, and most believe that it contributes to their safe practice of anesthesia.[180] In training settings where "practice improvement" is a specific target such courses can trigger credible efforts at personal or system change.[248] At the Stanford residency, ACRM has been extended to a multilevel course conducted over several years (i.e., ACRM 1, 2, 3). As the course levels progress, the scenarios become more complex and involve subspecialties of anesthesia. Besides, additional teaching modules cover other important aspects of organizational safety, such as systems thinking in morbidity and mortality conference settings or peer review settings, follow-up response to severe adverse perioperative events, and disclosure to the patient or family of bad news after an adverse event.

ACRM courses and ACRM-like variants are now offered worldwide and are often mandatory for trainees (and in some cases for experienced personnel). Salas and colleagues published an excellent critical overview about prerequisites for effective CRM training.[251]

BENEFITS OF CRISIS RESOURCE MANAGEMENT-BASED SIMULATION TRAINING

The literature on published benefits of CRM training effects is large; here are a few examples. Knudson and colleagues found a significant improvement in overall and teamwork scores in surgical residents taking care of critically injured simulated trauma patients if the residents had undergone CRM-like simulation training.[90] In a simulation study, no-flow time rates were significantly lower after CRM training paralleled with improved leadership verbalization.[153] A study in a multidisciplinary obstetrical setting involving anesthesia professionals showed a significant improvement in interprofessional teamwork and improved stress recognition after a CRM intervention.[220] In a prospective 3-year cohort study Haerkens and colleagues showed a decline in serious complications and the standardized mortality ratio, decreasing occurrence of cardiac arrests, and improving cardiopulmonary resuscitation success rates

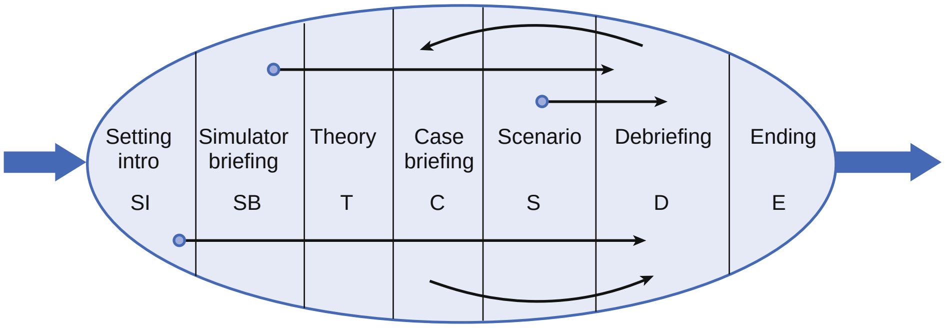

Fig. 7.18 Anatomy of the simulation exercise. A simulation exercise consists of different modules or different phases (e.g., simulation introduction *[SI]*, simulator and clinical environment briefing/"familiarization" *[SB]*, theory input *[T]*, case briefing *[C]*, scenario *[S]*, debriefing *[D]*, ending *[E]*). This figure shows a typical flow for a simulation course. If more than one scenario takes place during the course, the sequence form [C] to [D] is repeated for each scenario. The different modules are interrelated, and problems arising in one module can affect other modules *(thin arrows)*. (*Figure with courtesy of P. Dieckmann.*)

after a CRM-based intervention in a 32-bed ICU.[252] Moffatt-Bruce et al. published a significant reduction rate of adverse events and described return on investment after a system-wide implementation of CRM in 12 different hospital units including perioperative staff.[253]

Anatomy of a Patient Simulation Team Training Exercise

Whenever simulation is used it is important to consider its conceptual basis and the contextual factors that influence its use.[254,255] Therefore, with a focus on (CRM-oriented) mannequin-based patient simulation conducted for health care professionals, the next subchapters (1) give an overview of the training setting and important elements of a simulation exercise; discuss (2) the design of simulation scenarios and their execution; and (3) the modalities of the professionals' debriefing after a simulation scenario. Even though focused on the mannequin-based patient simulation conducted for health care professionals, many of the conceptual approaches presented below are identical or need to be modified only slightly to encompass other choices in the 12 dimensions of simulation.

Simulation activities vary in terms of goals and objectives. Most of the time, simulation scenarios are integrated into a multifaceted curriculum, which itself must be situated relative to the overall educational and training pathway of individuals and groups. Hence, for any given simulation activity both the conceptual and physical setting influence how the exercise is conducted, how it is perceived by participants, what participants learn, and which learned items are applicable in the clinical work domain.[255]

A simulation course/training itself can be divided analytically in different, interconnected phases as shown in Fig. 7.18.[255] Not all phases need to be present at each exercise and conversely some phases—like "scenario" and "debriefing"—may be repeated several times in a longer session.

Optimally the interconnected phases of the simulation exercise should be coordinated. If, for example, the briefing/familiarization is inadequate, participants may not be able to properly immerse themselves in the scenarios and debriefing might be impaired. The role of the simulation instructor changes throughout the different phases of the simulation training—from providing instruction in the beginning of a course to facilitating learning during debriefing. Based to a large extent on the work of Dieckmann,[255] the different phases of a simulation exercise (see Fig. 7.18) are discussed next, using the timeframe and elements of a simulation-based course as an example.

Pre-Briefing (PB). The pre-briefing introduces or reminds participants in advance about the course, its goals, and processes to appropriately situate the activity in their overall training, establish a positive attitude, and review the schedule of activities. An exercise that can be useful (stemming from advice from Ruokamo and Keskitalo from the University of Lapland) is to ask and discuss with participants "what do you want to learn or explore" in today's simulation course?, and similarly to ask the instructors "what are you interested in teaching or exploring?" This conversation engages the participants and demonstrates the instructors' interest in trying to address many of the preferences of the learners.

Simulation introduction (SI). An important aspect at the beginning of a session is to provide an overview about the course and the rules and norms of conduct for the set of exercises.[256] It is also important to provide a shared understanding for the simulation participants of the events that transpire during the course.[111] Besides, it is important to create a positive atmosphere to maximize learning, often referred to as *"psychological safety,"* or as recently published a *"safe container."*[121] Edmondson has defined psychological safety as *"the shared belief that the team is safe for interpersonal risk taking."*[257] Often this has a lot to do with ensuring the confidentiality of the simulation environment (i.e., "what happens here stays here") and that debriefings will "critique the performance, not the performer." Psychological safety *"is not about creating a comfortable space, it is about making it 'ok' to be uncomfortable."*[258]

Simulator and clinical environment briefing (SB) ("familiarization"). Participants need to be familiar with the simulator and the simulated environment in order to perform the closest to reality as possible, and they should not be distracted by technical or procedural uncertainty during the scenario. The participants can best master the scenario and actively engage in it if they know (1) how the simulator works ("normal" breathing sounds, "normal" pulses, intubation, intravenous access, etc.); (2) what it is able to do or not do; (3) how the simulated environment works (how to call for help, how to use the simulated equipment, etc.); and (4) what participants are able to perform on the simulator and what they need to pretend doing. Familiarization is characterized through explanations, demonstrations, and hands-on time for the participants themselves. This phase is very important in order to help the participants to make the best use of the simulation experience during the scenario. The plastic mannequin is on the way to being seen and treated as a patient. The more comfortable participants feel with the simulator and the simulation equipment, the less they will be scared or tense during the scenario. And more reflective learning about medical and non-technical skills can take place during the debriefing because the debriefing will not become about discussing the confusions and challenges regarding the simulation technology or environment. Therefore, it benefits both the instructor and the participants to have enough time for the familiarization process.

Presentation or discussion of theory (T). Theories of human performance or of clinical work processes might or might not be part of the course. Most exercises have didactic or theory components on relevant content information. Those components can either serve for transfer of (new) medical or technical knowledge, or for a refresher lecture on certain algorithms, but also for the introduction of (anesthesia) crisis resource management-related skills (ACRM, CRM) and patient safety issues (Chapter 6). Sometimes educational material is made available in advance through readings or online exercises. Sometimes lectures or group-work modules are put in place at different junctures of the training.

Breaks (B). For complex and long-lasting courses breaks are important for recreation and for socialization among participants and with instructors. Breaks provide a venue for informal sharing and storytelling, one of the many learning opportunities during a simulation training outside of a simulation scenario.

Case briefing (C). Because the simulator is not a real patient itself providing clinical information and because the environment of a simulation imposes several challenges, there are different ways to ensure that participants have certain relevant information concerning the case and the simulation reality before, or at the beginning of, the scenario. Sometimes it is natural for a participant to take over a case from another clinician (in fact in ACRM starting every case from the beginning would waste a lot of time). Such a handoff can be scripted to be complete or cursory as appropriate. In other cases the context information can be presented verbally or in written form by an instructor. Other information that would not be readily available in context might include the look or smell of the patient or the specific location of care (e.g., main OR vs. off-site ambulatory surgery center).

Simulation scenario (S). The scenario and—when possible—the debriefing together form the core of the learning experience during simulation. Simulation scenarios are more than clinical cases. They are the vehicle to reflect on medical knowledge as well as personal and team performance in a safe learning environment that elucidates similar behaviors as during real-world cases. Most simulation exercises involve a scenario that simulates a given clinical situation, challenging the participants to deal with the situation at hand. The scenario is designed in advance by the instructors in accordance with the learning objectives of the training (see later subchapter on scenario design). During the execution of the scenario, the instructor (or simulationist/simulation technician) regulates the responses of the simulator and adapts the scenario flow[259,260]; gives relevant patient, situation, or clinical information to the team that the simulator or clinical personnel does not provide itself[260,261] (see later subchapter on live in-scenario guiding); manages the exercise to enable participants to optimally act as if[259] treating a real patient (see later subchapter on scenario design).

Debriefing (D). Most training scenarios are immediately followed by some form of feedback or debriefing, respectively. Fanning and Gaba give an overview of the origin and background, the role, the models, the structural process, the elements, and several other modalities of debriefing in simulation-based learning in their recommended review.[238] The learning objectives, the target audience, and the simulation modalities drive the decision whether a debriefing is useful and if so how in-depth the debriefing process needs to be. In some courses, feedback is only minimal, whereas other courses have a dedicated debriefing session after each scenario that take as long, or even longer, than the scenario itself (see later subchapter on debriefing techniques). Several different debriefing methods exist.[24,105,109,110,238] Debriefing can be facilitated sometimes by strategically presenting snippets of the recording of the scenario.[117,238]

Ending (E). Especially for multiple-scenario courses, a separate final session may be included to end the course. This phase represents an opportunity to summarize issues that were covered and to reflect on how best to apply these lessons to real patient care.

Scenario Design and Execution: Knowing the Learning Objectives and Making It Real

The design of scenarios for interactive simulation team trainings can be tricky and typically differs from preparing training exercises for traditional curricula.

"The key is the program, not the hardware"[62] was a truth about simulation learned early in aviation simulation and similarly possesses validity for the scenario design and execution with patient simulation. Using simulation in a goal-oriented way is at least as much about the conceptual aspects of the technique as it is about the technology of the simulation devices. An understanding of the conceptual and theoretical aspects of simulation is helpful for determining the right applications of the technique and the important matchups to be made in the design and conduct of simulation exercises to obtain the best results. When used most effectively, simulation can be—to borrow a line from the music band U2—"…even better than the real thing."

In the following sections the design and conduct of scenarios for a patient simulation are touched on more closely, considering (1) establishing learning objectives; (2) applying cognitive load theory to scenario design; (3) pointing out constraints and limitations of the design, discussing

(4) conceptual issues of reality, realism, and relevance; and (5) in-scenario information and guiding.

There is a vast aggregation of literature concerning instructional design for all kinds of simulation applications. For detailed information the reader is referred to further literature.[23,77,115,177,262] The topic is covered extensively in most of the instructor training curricula that are offered at sites around the world. International and regional simulation meetings (e.g., the International Meeting on Simulation in Healthcare [IMSH] of the SSH, or the annual meeting of the Society in Europe for Simulation Applied to Medicine [SESAM]) often provide workshops on scenario design. The user groups of the major simulator manufacturers also have workshops on the topic.

The following sections can only serve as an introduction to the topic and again focus mainly on (CRM) mannequin-based patient simulation conducted for health care professionals.

GOAL ORIENTED: ESTABLISHING LEARNING OBJECTIVES

Learning objectives provide the reason and frame for the simulation scenario. They contain clinical and technical skills, or non-technical skills such as communication, leadership, teamwork, situation awareness, decision making, and task management (see Crisis Resource Management, CRM, Chapter 6). Optimally, scenarios are chosen that stress the individual's diagnostic and problem-solving abilities, the clinical and technical knowledge, and the core aspects of CRM.[75,217]

Learning objectives can be preset by a curriculum, determined via needs analysis, intuitively known by the simulation-savvy clinician educators, or learned about in instructor training or in the literature. Learning objectives operationalize relevant questions by defining who should be able to do what and in what situations.[78]

Simulation scenario design may be thought of in a stepwise, layered fashion. Research in work psychology suggests that, for the purpose of learning, it is helpful to de-construct complex tasks into phases and hierarchical levels. For example, the scenario "resuscitate the patient" includes three main goals: (1) diagnose cardiac arrest (subgoals: check pulse, check breathing, check "brain"), (2) oxygenate brain (subgoals: open airway, cardiac massage, ventilate), and (3) reestablish spontaneous circulation (subgoals: defibrillate, administer epinephrine) which require team members to coordinate (e.g., ensure that all team members know diagnosis, distribute task).[263] This insight into what behaviors are expected of a team during the scenario facilitates not only the design of the scenario as such,[115] but it also helps educators to direct their attention while observing the team's performance and possibly sharing the workload among them by distributing observational tasks in the co-debriefing setting.[264] Furthermore, it helps educators to guide the debriefing.[107] Learning objectives and performance expectations should be considered in advance in order to use the debriefing to close potential gaps and guide teams to maintain good performance.

COGNITIVE LOAD THEORY: NOT TOO MUCH, NOT TOO LITTLE

When designing and conducting simulations the learning opportunity would ideally match the abilities and learning needs of the participants. If the scenario is too difficult, participants' can be overwhelmed and their learning likely compromised. Conversely, if the scenario is too easy, participants will find no challenge, may be bored, and won't learn very much. Cognitive load theory[265] provides a framework to distinguish different aspects in a learning situation that illuminate the "difficulty" of a scenario so as to optimize it for learners. In this theory, three different forms of cognitive load are distinguished. The overall difficulty can be thought of as the sum of the following three parts: (1) Intrinsic cognitive load, which describes the complexity/difficulty of the material to be addressed. This depends somewhat on the learner's prior knowledge but beyond that some issues are just more complex than others for most. (2) Extraneous load, which stems from the presentation of the material to be learned, e.g., a well-structured textbook might make learning easier compared to a chaotic lecture. (3) Germane load, which describes the internal processes and the cognitive energy needed to process information.

Cognitive load theory would suggest, for example, that asking novice anesthesia professionals to manage both a complex clinical situation and a challenging interpersonal one may result in overload. Unfamiliarity with simulation will also raise the extrinsic load—participants have to interpret the pretend situation as if it is the real thing, making it difficult to concentrate on the lessons to be learned. The germane load might be increased when participants are concerned about being observed. They not only need to consider what the best course of action in the scenario might be, but, at the same time, also try to manage the impression that they make on the instructors and observers.

A good simulation scenario will take these different elements into account. Extraneous load can be optimized by carefully designing scenarios and by PB instructions.[255] Germane load might be optimized by helping participants become more familiar and comfortable being in simulations, for example, by well-designed simulation familiarization, or by increasing the complexity of scenarios slowly.

CONSTRAINTS AND LIMITATIONS OF SCENARIO DESIGN IDEAS

It is easy to suggest a scenario on paper but more difficult to translate it into an effective scenario for actual use. Limitations and constraints of the available simulators, personnel resources at hand, the props or external systems that would be needed, and the time needed to set up and run the proposed scenario must be considered. Most scenarios are first generated with a core idea, a "kernel" that is then fleshed out by discussion in an iterative fashion, with creative redesign or minor technical modifications. Ideally the new, redefined scenario is tested out first by instructors and technical staff, or pilot-tested with a volunteer group of participants from the target population. With highly experienced instructors a new scenario may need only a technical walkthrough before it is run for real participants. All scenarios can get better with time as glitches are found and refinements made.

SCENARIO DESIGN TEMPLATES AND SCENARIO TEMPLATES

Many centers have developed design templates for the development of their scenarios. Box 7.5 shows the key questions

BOX 7.5 Key Considerations for Simulation Scenario Scripts

Based on script templates provided by Dieckmann and Rall (https://www.inpass.de/downloadshtml/downloadscenarioscript/), the key information a scenario script should provide includes:

- Scenario name (quick reference)
- Major medical challenge of scenario
- Major cockpit resource management (CRM) challenge of scenario
- Learning goals (medical and [!] CRM)
- Brief narrative description of scenario
- Staffing (instructor/simulation team and participants)
- Case briefing (all participants together or separate briefings for different teams)
- Simulator setup and mannequin preparation
- Props needed
- Scenario "lifesavers"[259] for both excellent and bad performance of participants

Usually, the scenario script contains (1) a summary sheet with brief notes of the above mentioned topics and (2) a more detailed description of the scenario in regard to those questions on several other pages. The proper use of scenario scripts is a regular part of many instructor training courses.

for the design of scenarios. Long scenario templates that are freely available include Dieckmann and Rall's (https://www.inpass.de/downloadshtml/downloadscenarioscript/) and the Duke University template (https://anesthesiology.duke.edu/?page_id=825706). Some journals publish detailed scenario descriptions and some professional societies have created scenario repositories for members; the American Society of Anesthesiologists (ASA) Simulation Committee has a repository for scenarios to be shared among its ASA-endorsed simulation programs. By now, many scenario templates are freely available on the Internet. In general, long and detailed templates are only needed when a scenario is to be shared widely, or when there is a need to formally document it. Simpler templates will likely suffice for in-house use by a single simulation center.

REALITY VERSUS REALISM

Simulation is a complex social undertaking.[155] The concepts discussed in the upcoming section concern the nature and the impact of "fidelity" and "realism" as they apply to simulation and the goals of simulation. Both are terms widely used, and misused, in simulation design. In this chapter the concept of relevance is covered briefly. All three concepts are important components of engaging participants during simulation, an important aspect of conducting meaningful exercises.

A patient simulation exercise is itself a real occurrence that is actually happening. The exercise is a *reality*, but it is intended to represent another reality in the real world of patient care. Hence, it may or may not be perceived that way. *"Realism"* addresses the question of how closely a replication of a situation is needed to meaningfully represent this situation to participants. Aviation simulators, for example, are so realistic now that pilots with experience flying one aircraft are routinely certified to fly a totally new or different aircraft, even though they have never flown the actual aircraft before. Nestel, Krogh, and Kolbe explored realism in health care simulations in detail.[266] In their work, the authors also use the term *"meaningfulness"* in proposing strategies to help simulation educators make sense of decisions about realism.

There is an important distinction between the realism of a *simulator* (a device) and that of a *simulation* (the exercise). For example, a simulator could be indistinguishable from a real human being (e.g., an actor playing a standardized patient) and yet be used in an implausible and useless fashion, so that the simulation itself is not realistic. Conversely, certain kinds of simulation realism can be evoked by exercises that use simple simulators or even no simulator at all (see below).

It is naïve (though frequent) to think that greater realism of a simulation exercise will automatically lead to better achievement of its goals. Maximum "realism" is neither needed nor desired for every type of simulation endeavor. For some applications with some target populations, it can be highly advantageous to reduce the realism to heighten the learning experience.[157] On the other hand, merely creating a realistic simulation does not guarantee meaning or utility (e.g., learning) for the participants.[155,156] The different concepts and explanations with regard to this matter have been discussed repeatedly in the literature.[155-158,260,267-269] However, as "realism" is a complicated set of ideas in simulation, results of studies trying to investigate roots and effects of simulation realism are not conclusive, in part because each study may concentrate on a different aspect of the complex whole. Different fidelities and dimensions are used to describe or achieve the realism of simulation, as described in the following.

Different (practical) fidelities to create simulation realism. Alessi[270] defined fidelity as the "degree to which a simulation replicates reality" (p. 203). Several concepts about simulation fidelity exist.[198,260,271] These include physical fidelity (the device replicates physical aspects of the human body), environmental fidelity (the simulation room looks like the relevant clinical site), equipment fidelity (the clinical equipment works like or is the real thing), and psychological fidelity (the simulation evokes behaviors similar to the real situation). Realism is thought to be achieved by various forms of validity, such as face validity (looks and feels real to participants), content validity (the exercise covers content relevant to the target situation), construct validity (the simulation can replicate performance or behavior according to predefined constructs about work in real situations), and predictive validity (performance during a simulation exercise predicts performance in an analogous real situation.

Different (theoretical) dimensions to create simulation realism. In 2007, Dieckmann, Gaba, and Rall published an article attempting to clarify some issues about realism, reality, relevance, and how they influence the purpose of conducting simulations.[155] In their article, they applied the model of thinking about reality by the German psychologist Laucken to the realism and fidelity of simulation. Laucken described three modes of thinking about reality: physical, semantic, and phenomenal fidelity. Another publication on modes of thinking about reality was published by colleagues from Boston.[158] Apart from those definitions a variety of terms exist to describe conceptual simulation design, in particular with regard to fidelity. To gain a better understanding of the various terms and their meaning, Paige and Morin published a systematic review article on that matter and additionally suggested to divide the concepts of fidelity into physical (including environmental and equipment), conceptual, and psychological.[260] The ideas and concepts presented below are largely contributed by Dieckmann and his adaptation of broader psychological concepts to simulation in medicine:

Physical mode of realism. The physical mode concerns aspects of the simulation that can be measured in fundamental physical and chemical terms and dimensions (e.g., centimeters, grams, and seconds). For example, the weight of the mannequin, the force generated during chest compressions, and the duration of a scenario all are physical aspects of simulation reality. Despite their roughly human shape, existing mannequins have many unrealistic physical elements, for example they are made of plastic, not flesh and bone; they may have unusual mechanical noises detectable during auscultation of the chest; the "skin" does not change color.

The physical mode of simulation also relates to clinical equipment and the clinical environment. (1) Some equipment used in mannequin-based simulation is fully functional and physically identical to the real thing. Labeled syringes may contain only water instead of real medications. (2) An ISS in an actual hospital room and bed has a higher physical realism than does the same equipment in a conference room.

Semantic mode of realism. The semantic mode of realism concerns concepts and their relationships concerning clinical information and its meaning. For example, in a simulation of hemorrhagic shock, how does the participant make sense of what is going on? Within the semantic mode, a simulation of hemorrhage could be described in semantical terms as "bleeding" of flow rate x beginning at time y occurring at site z that is associated with a blood pressure of b that shows a decrease after some time from the prior value of a. It is semantically irrelevant how the information is transmitted or represented. The same pieces of *information* could be represented either using a vital signs monitor, a verbal description, or the tactile perception of decreasingly palpable pulses. The semantic mode allows the simulation exercise to represent a real situation. It allows lifeless, rosy, smiling simulators to be treated as if they were real patients. It allows water-filled syringes to be treated as if they contain effective drugs.

PATIENT SIMULATION ACTION BOX

If the right and sufficient clinical information is given to the participants at the right time, in their minds the inanimate mannequin can become a severely ill patient (see later section on "in-scenario information and guiding"). At the same time it is important for instructors to remember, in particular during the debriefing, that because meaningful simulation depends on interpreting information, it is not always interpreted by participants the way that the instructor imagines it will be.

Phenomenal mode of realism. The *phenomenal mode* deals with the learner's engagement and experience in the simulation including emotions, values, motivation, self-awareness, and beliefs. If participants are fully engaged in the simulation, then they are likely to act as if they are treating a real patient in the real clinical environment. For many purposes, providing high phenomenal realism is the key goal, but sufficient physical and semantic realism are means to this end.

PATIENT SIMULATION ACTION BOX

A good simulation scenario does not necessarily need to be designed as realistic as possible, for example having artificial blood all over the mannequin during a trauma scenario. A good simulation scenario can create the appropriate sense of realism by a combination of the following:

(1) … the simulator and environment used
(2) … the case presented, the team composition, and the professional role of each participant
(3) …clinical equipment used, or sufficient semantic equivalents
(4) … the briefing before the simulation case starts
(5) … instructor feedback when the simulator is examined (see later section, "live in-scenario information and guiding"). The application of those aspects is not trivial; they influence the way the simulation is perceived by clinical professionals.

SIMULATION REALISM AND SIMULATION RELEVANCE

The relevance of a simulation exercise concerns the match between the characteristics of the exercise and the reasons for which the exercise is conducted. Scenarios should be relevant to the trainees, but this depends on many factors, including the trainees' backgrounds and experience, the method of conducting the scenario, and related parts of the simulation course (e.g., familiarization with simulator and simulated environment, case briefing, etc.).

In fact, it is worth utilizing unrealistic elements ("unreality") in order to maximize the learning—a useful slogan is "the point is not to 'fool' them but rather to teach them." So, for example, when training on invasive procedures, it is typical to forego phenomenal realism and emphasize physical and semantic realism so that psychomotor skills can be the focus. Similarly, physical realism may be sacrificed when necessary by time compression or expansion. Boring parts of a case may be skipped for experienced personnel whereas for inexperienced clinicians situations that could become lethal extremely quickly (e.g., swap of N_2O for O_2 in the pipeline) may be slowed down so that inexperienced clinicians can try to think their way out of the problem. If such a situation were allowed to evolve at its normal speed, it would transition to management of cardiac arrest before the participants could deal with the original problem. Other uses of "unreality" include cognitive scaffolding, which provides various forms of assistance—sometimes a teacher or coach in the simulation room—or extra cues to help participants as they struggle with decision making and therapy selection.

IN-SCENARIO INFORMATION AND GUIDING

Although full-scale mannequins mimic a wide range of human features, they differ from the body of an actual patient. This gap implies a need for simulation instructors to provide in-scenario information to help participants understand scenarios. In-scenario information and guiding may also be needed to help (early) learners progress in the scenario if they are stuck or on the wrong path. Different terms such as clues, triggers, prompts, hints, and instructional support have been found in the literature associated with the concept of cueing in a simulation activity.[260] Dieckmann et al. used the unique phrase "scenario life savers."[259] Many cues and "life savers" can be used within the logic of the scenario in ways that do not disrupt the experience.

In general, one good way to feed information to participants in patient simulations about various phenomena that cannot be simulated physically is to announce the missing signs, symptoms, or examination results. Escher and colleagues summarized four methods that instructors used to provide such extra scenario information and how the different methods to convey information affected how scenarios played out.[261] The methods found included cues from (1) confederates, (2) bystanders, (3) loudspeakers from the control room to the scenario room, or via (4) an earpiece. Even though Escher et al. conclude that the mediation of information by a loudspeaker or an earpiece from the adjacent control room could be disturbing for team communication, the authors of this chapter see several advantages in the use of in-scenario audio guidance. In their opinion, audio guidance is especially helpful for feedback in those kind of situations: (a) physical examination results, such as (misleading) auscultation results, or results of abdominal palpation but usually only after the participant has credibly attempted to obtain that result physically; and (b) *immediate* correction of mental models that are not in line with the scenario (i.e., (misleading) auscultation apparently indicates pneumothorax, but there is in fact no pneumothorax).

This kind of in-scenario semantic information is incorporated by participants into their mental model of the situation at hand during the simulation and helps them to "stay in" the simulation despite physically treating a plastic mannequin.

Debriefing: Heart and Soul of Patient Simulation

As introduced in the section on the "anatomy of a simulation course" (see Fig. 7.18), conducting simulation training is not only about running the simulation scenario but equally about how, in debriefing, the participants are facilitated to reflect about what they experienced. The philosophy of teaching and learning in a debriefing of a CRM-based simulation course differs from the traditional clinical teaching style (Table 7.3).[238] For more information on debriefing in health care simulation the reader is referred to further literature.[24,105,109-111,113,238,272-276] This chapter can only serve as an introduction to the topic and focuses mainly on patient simulation with focus on (CRM) team training.

TABLE 7.3 Traditional Teaching Versus Facilitation in Simulation Training Courses

Traditional Teaching: "Teacher"	New way of teaching: "Facilitator"
Focus on theoretical or clinical knowledge only	Focus additionally on human factors/ CRM
Focus on "what" happened/"what" or "who" was *wrong*	Focus on "why" things went wrong (deeper analysis) *and* on "why" things went well
(T) is the (absolute, infallible) expert.	(I) possesses expertise, but moderates different ideas on eye level, uses knowledge and expertise of (P), discusses own views with peers.
(T) tells participants what to do better next time.	(I) helps (P) to find out root causes for their performance, examines possible solutions together.
(T) knows what is right / important for (P).	(I) helps to self-reflect, gain realistic self-awareness / consciousness; (I) guides debriefing toward interesting areas, but is open for topics relevant to (P).
(T) speaks the most during feedback.	(I) stimulates and guides discussion among participants during debriefing, but does not speak the most.
(T) is a domain expert.	(I) additionally is a CRM expert.
(T) has no special training in patient simulation-based learning.	(I) has special training and/or experience in patient simulation-based learning.
(T) makes no video-assisted feedback.	(I) makes strategic use of video when relevant to enhance debriefing.
(T) determines whether (P) has learned the intended lesson.	(I) gauges whether (P) is engaged in discussion and understands relevant issues but (P)'s experience is too complex to assess simply

CRM, Crisis Resource Management; *(I)*, Instructor/Facilitator; *(P)*, Participant; *(T)*, teacher.

SIMULATORS (DEVICES) DON'T TEACH

Most simulation training exercises involve some kind of feedback or debriefing that can be given in many different ways and settings.[111,113,238,272-275] The terms *debriefing* and *feedback* are often used synonymously, but there exists a difference in their meaning. *Feedback* is used with the intention to modify thinking and / or behavior and generally involves comparing the observed performance to a standard (whether formally or informally defined). Usually it is a one-directional flow of information about the performance from the instructor to simulation participants.[111] *Debriefing* refers to a special time and format for discussing an episode of action in the past; it is the counterpoint to a briefing, which occurs before an action or task. In contrast to feedback, debriefing is viewed as a bidirectional, interactive, and reflective discussion or conversation that *"may occur between simulation participants and facilitators [instructors], or among participants themselves, or some combination thereof"* [p. 209].[111]

In medicine, inspired by its use in aviation CRM, the debriefing concept was introduced to simulation training by Gaba and colleagues as part of ACRM simulation training for anesthesia teams.[181,217] Over the years debriefing after simulation training has been refined so that it has become an indispensable component of many simulation curricula.[273]

INSTRUCTION VERSUS FACILITATION—A NEW WAY OF TEACHING

In many learning contexts, the person who is in charge of the training usually is referred to as "instructor." In the debriefing idea described above, the instructor's role changes from an "instructor" to a "facilitator": instead of constantly instructing, the instructor's role is to *facilitate* the learning process. This is accomplished by *directing the participants* to the most interesting and important areas for consideration, *stimulating discussion* among participants to *find underlying issues* for their performance and *seeking individual solutions for future events* of similar type. For most instructors, *facilitation* is a new way of teaching and often must be learned, even if they have many years of traditional instructor teaching experience. In the simulation arena the term instructor refers to an individual who is responsible for overall direction of a simulation scenario; that person is often—but not always—one of the facilitators for the debriefing.

Fruitful discussion and learning can be triggered by reflecting on both aspects of performance that worked well and those that were difficult or problematic (see also "Safety II", chapter 6). In their paper Dieckmann et al.[277] describe the "learning from success" approach to simulation and debriefing drawing on several theoretical frameworks.

PATIENT SIMULATION ACTION BOX

Ideally, the clinical expertise of the simulation participants should be represented in the clinical expertise of the instructors. For an interprofessional trauma team training, for example, it would be best to have instructor(s)/debriefer(s) from each of the relevant professions and disciplines, especially from anesthesiology, nursing, and surgery.

DEBRIEFING TECHNIQUES

Although debriefing styles differ at institutions, sites, and individuals around the world, a common ground is shared by most simulation-based educators: debriefing should *stimulate self-reflection,* and it should unpack *how* and *why* things happened the way they did.

Reviews of debriefing techniques in simulation by Fanning and Gaba,[238] Cheng et al.,[113] and Sawyer et al.[111] indicate the broad range of literature available regarding debriefing, and highlight the many models and approaches that can be used. Debriefing most commonly occurs soon after a scenario run, but the same techniques can be used during pauses in the simulation. Although it is possible for participants to debrief themselves, this would come with limitations due to lack of structure. Usually a post-event debriefing is guided by a facilitator.[111]

A variety of approaches to debriefing exist, each with its own structural phases and several conversational structures.[238] These include Debriefing with Good Judgement,[105-107] The Diamond,[108] SHARP,[278] PEARLS,[109] TeamGAINS,[110] Alternatives and Pros & Cons,[238] and others.[111-114] These conversational structures guide the flow and the context of the debriefing and divide it into various phases, each serving a specific focus and purpose. Whereas the phases differ, Sawyer and colleagues summarize that most frameworks highlight the importance of guiding the conversation from a beginning, through an examination of events, and then relate the aspects most relevant for clinical practice.[111] An example of a debriefing structure is shown in Table 7.4.

Although it is clear that debriefing plays a crucial role in simulation exercises,[119,198,279-281] there is little evidence supporting one format over another. This should not be surprising because the goal is broad, the experience of simulation is intense, and participants' interpretations and discussion are rich.

A qualitative interview study[275] with 24 expert debriefers showed that for experienced debriefers it is not about the specific concept, but about the sets of ideas and beliefs that represent the values and teaching philosophy used: *"the debriefer is a facilitator, who must be dedicated, honest, genuinely curious and possess the abilities to facilitate a reflective debriefing [....] following the learners needs and objectives [...]"* (p. 3).[275]

Apart from applying a similar structure to the debriefing, revealing one's stance and frames, and creating a safe learning environment, most experienced debriefers blend several debriefing models and conversation techniques and adapt them dynamically, depending on personal preferences, the learners' perceived needs, and the scenario as experienced by the debriefer.[275] Asking open-ended questions in order to facilitate the discussion and foster self-reflection and self-assessment on the part of the participants as well as using silence after a question asked by the instructor are other key elements of facilitated debriefing.[111] During this silence, internal thinking processes on the part of the trainees are taking place. Open-ended questions cannot be answered with "yes" or "no" and therefore trigger the participant to explain the situation from his or her point of view. Some facilitators, especially when they are not highly experienced, use a debriefing script or a cognitive aid to help them lead the debriefing conversation effectively. On the other hand, sometimes the debriefer can just sit back and listen; the best debriefings may be when most of the discussion is purely between the participants themselves, addressing issues that are on target for the instructor's purposes, in which case the facilitator will need to use very few specific techniques of debriefing.

For instructors, preparing for a good debriefing starts during the conduct of the scenario. A key skill for the debriefer is to be able to watch and listen carefully to what is happening in the scenario while also attending to the tasks of running it (Fig. 7.19).

For immersive, simulation-based team training, the debriefing sessions usually last approximately as long as the scenarios themselves, although a complex scenario may well generate a nuanced conversation that could go on for much longer. For shorter simulation activities, such as unannounced mock resuscitations, debriefings have to be much shorter. The number of debriefers can vary. Some prefer to have a single debriefer (or there may be only one

TABLE 7.4

Phases of debriefings: Issues relevant to (anesthesia) crisis resource management-based simulation debriefing.

The listed phases do not necessarily all have to be followed in this time sequence and order. Depending on the scenario, the participants' performance, and the debriefing format, several phases have to be repeated within the debriefing, especially during the debriefing center part, as indicated with the circle. Sometimes phases overlap when discussing the scenario.

PHASE OF DEBRIEFING		Explanation
Pre-Debriefing	Ending the scenario	If possible, the (SC) should not be stopped too early. (P) should be allowed to realize the natural end of (SC). Ideally, (SC) should not be terminated when (P) are in the thick of it, e.g., still caring for the patient and applying treatment measures.
	Scenario-to-debriefing transition	Most sites use debriefings immediately following the simulation. This allows the (I) to hear and see (P)s' direct reactions. A variant is to give the (P)s a few minutes to discuss the (SC) itself while the (I) is planning the (D).
Debriefing Start	Emotional venting	All (HS) are given the opportunity to say how they *felt* during the (SC). This vents pent-up feelings and may be a time to deal with anomalies in the (SC) (e.g., simulator malfunction, simulation artifact, etc.). In this phase, (P)s also can critique the (SC)—critique that the (I) should acknowledge and take seriously.
	Descriptive phase	(P)s describe what happened (or portions of the audio-video recordings are replayed) and what the clinical problem in the scenario was. Different points of view are shared (e.g., doctor vs. nurse vs. first responder vs. surgeon, etc.).
	Self-identification of issues	It is sometimes useful to ask (P) to identify issues that did not go well or what they would do differently, in order to give them the opportunity to critique themselves before anyone else does. Nevertheless, the (I) can and should help identify what the underlying causes were and the pros and cons of alternate approaches.
Debriefing Center Part	Discussion of clinical content	Any major issues of clinical treatment and related CRM points should be covered. A (D) should not end without discussing and clarifying any significant clinical errors and ensuring that participants understand the correct clinical management.
	Analysis	(D) should provide considerable analysis of *why* things happened vis-à-vis the intentions of all parties, as well as alternatives and their pros and cons.
	Transfer to the "real world"	Participants can discuss how lessons from the scenario or debriefing can be applied in the real clinical world. They should discuss barriers to improvement and ways to overcome them.
	Opportunities for systems improvement	When applicable, based on the analyses, (P)s can be asked to suggest how the system can be changed to improve handling of similar situations in the future.
Debriefing End	"Take-Home-Message"	A summary of the learned key points of the (D), either by (I) or (P), can be useful.
	Terminating the debriefing	(D) are rich in content and easily can extend beyond the time available. Thus, giving a time frame for the (D) and officially marking its end is a useful transition to preparing for the next (SC) or the end-of-day activities.

"Hot Seats" (HS) = Participants (P) who were actively involved in the scenario (SC); Debriefing Room (DB); Simulation Room (SR); Simulation (S), Instructor (I), Debriefing (D), Crisis Resource Management (CRM).

Provided by M. Rall & P. Dieckmann as used in their own courses, derived from the original ACRM-course structure by D. Gaba and colleagues and used by many others around the world.

instructor) but often there are two or more "co-debriefers." Coordinating multiple facilitators can be tricky (it is sometimes described as being like dancing). Cheng et al.[264] described several effective strategies for co-debriefing.

Generally, faculty members intending to be debriefers in immersive simulation-based education need special training and practice in this teaching method[105,119,238,282,283] and continuous experience and training throughout their career.[275] Several simulation centers conduct instructor training that emphasizes debriefing skills, and debriefing is a frequent topic of workshops at large simulation conferences.

Box 7.6 shows a selection of the learning myths—especially in regard to the debriefing of patient simulation team

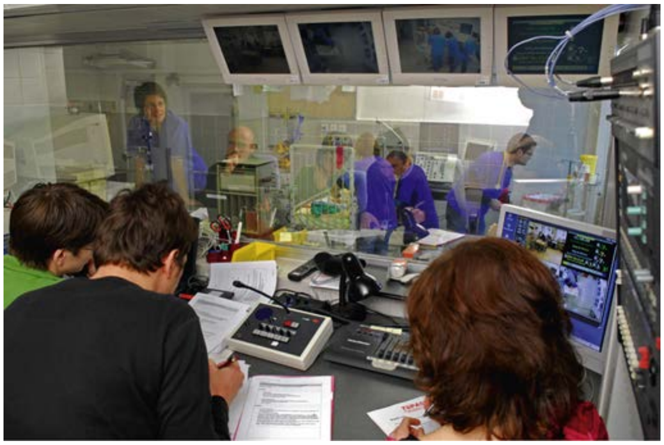

Fig. 7.19 High workload for instructors during a simulation case. The photograph shows the instructor team in front of the control panels and monitors in a control room during a simulation scenario. The control room is separated from the simulation room by a one-way mirror. The instructors have to operate the simulator, control the course of the scenario and the vital signs, give live in-scenario guiding, communicate with confederates who support the simulation in the scenario room, and at the same time take notes for the debriefing. These complex tasks need prior training or experience and good organization on the part of the instructor team. (*Photograph by B. Schaedle, Momentum Photo at University Hospital, Tübingen, Germany.*)

training—that seem to spread among medical educators, but are erroneous in the eyes of the authors, especially when training health care professionals.

USE OF RECORDED AUDIO-VIDEO SEQUENCES IN DEBRIEFINGS

In the initial ACRM simulation courses the debriefer and participants viewed the entire recording, pausing at points for discussion. This practice has been abandoned and today most debriefers use the recordings only strategically to trigger discussion of specific points.[111,119,202,283,284] Studies of debriefing provide varying results as to the utility of showing the recordings and there is no definitive proof that this deepens the debriefing experience.[116,118-120,285] Nonetheless, snippets of audio-video recordings are frequently used as a learning and self-awareness experience.[117,119,202,284] Some studies point toward a positive effect, others do not. As the process of debriefing is complex and the effects of simulation and debriefing are expected to be a long-term accumulation of learning, reflection, and change, it is not surprising that teasing out cause and effect is difficult.

One argument for the use of audio-video-triggered reflection is that anesthesia does not support much self-reflection during routine clinical work. Experienced anesthesiologists often work alone, and there is often little feedback from other anesthesia professionals or from other operating room personnel. Most cases are followed as quickly as possible with the next. The lack of peer feedback leaves a large gap between the way individuals think they perform and how they act in reality. Based on the experiential learning cycle of Kolb[286] (Fig. 7.20) the opportunity to witness one's own behavior via a recorded audio-video sequence can be more meaningful to clinicians than described behavior criticized by the instructor. Another argument is that viewing the live transmission of the simulated scenarios is

BOX 7.6 Erroneous Learning Myths in Simulation Training

Learning Myth No. 1: *"Participants always need to figure out themselves what they did wrong."* Although self-reflection can be powerful, instructors can and should be ready to point out examples of problematic decisions or actions that are relevant to the clinical setting and to stimulate discussion of the alternatives and their pros and cons. This may lead to better understanding of possible solutions and how different clinical contexts will affect which are preferred. If participants grasp the situation and possible solutions on their own that is great. But if not, debriefers should not make participants search for the answer they wish to hear (this is called a "guess what I'm thinking" question); rather, they can use their own experience to suggest approaches that have worked for them.

Learning Myth No. 2: *"You always have to say something positive before you criticize."* Educators describe the "sandwich" approach; the full sandwich has a filling of negative comment(s) sandwiched between two positive comments (a simpler "open-face" sandwich is also seen). Since debriefing is not "feedback" this is usually unnecessary. The discussion of what transpired and why should facilitate health care professionals learning from the analysis of all aspects of performance without special cushioning of the blows.

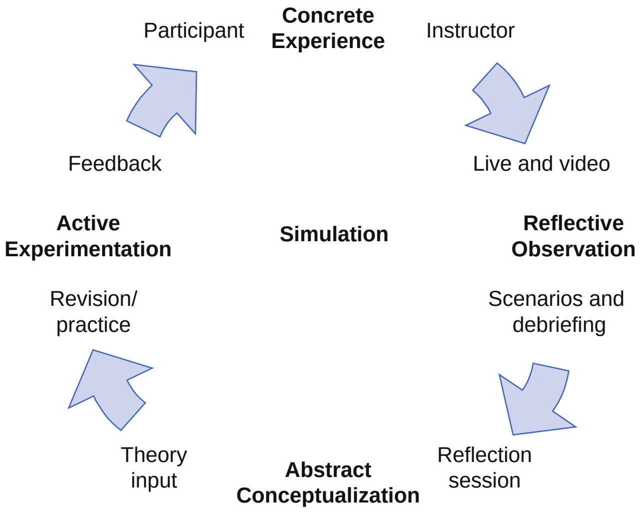

Fig. 7.20 Kolb's experimental learning cycle. Simulation team training with live video transmission and a debriefing with audio-video recordings demonstrates an ideal representation of Kolb's learning circle. During the scenario, actively involved trainees have a concrete "hands-on" experience. With the facilitation of the instructor and the own observation of audio-video sequences, the individual behavior can be actively reflected in the debriefing ("reflective observation"). The live video transmission to the non-active group during a scenario allows "reflective observation" during the scenario. During the debriefing, all trainees (active and non-active) have a phase of abstract conceptualization, in which the instructor uses generalizations of factors and root causes to show how behavior developed as it did in the scenario. With the instructor's theory input and the eventually triggered discussions, deep learning can take place and a plan can evolve during the debriefing, for both active and non-active trainees, of how to handle a similar situation next time. Active experimentation with the newly learned input and the drawn conclusions for the active as well as the non-active group can take place either during the next active scenarios or during real patient care. (Modified from Kolb DA. *Experiential learning: experience as the source of learning and development.* Englewood Cliffs, NJ: Prentice-Hall; 1984.)

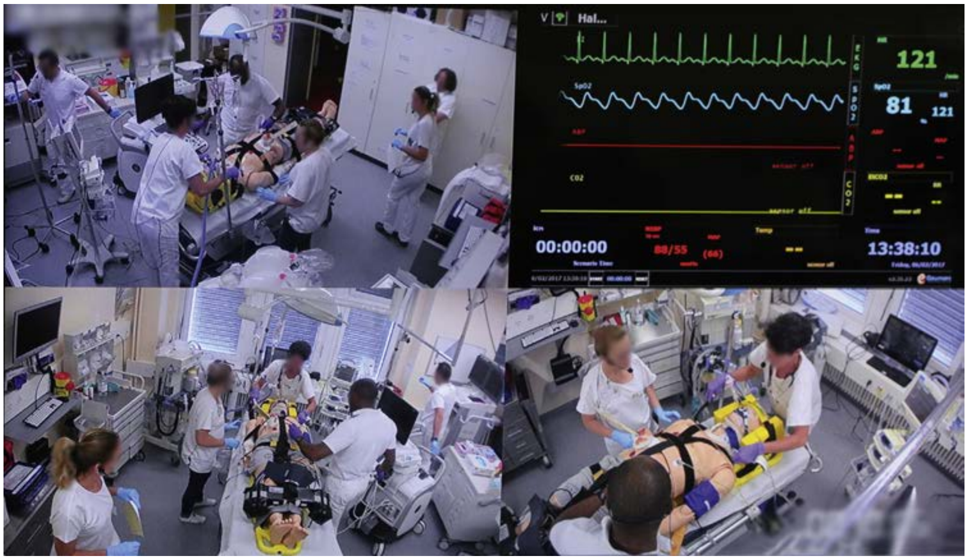

Fig. 7.21 Quad split monitor of a simulation exercise. The quad split of a simulation exercise shows the vital signs during the scenario and usually three different camera perspectives during a simulation scenario. The quad split can be used for the live transmission of the simulation scenario to the participants who are not directly involved in the scenario. And it also serves for the later audio-video-based debriefing to reflect what happened in a certain situation, providing the advantage of different angles of view and an isochronic view of the vital signs. (*Photograph provided by M. Rall, InPASS in-situ-training at Scuol Hospital, Switzerland, Chairman J. Koppenberg.*)

useful for participants who are not actively involved in a given scenario (see Fig. 7.20 and Fig. 7.21). There is evidence that observers of simulations can learn as much as participants.[287]

Advanced simulation course formats generally closely reflect Kolb's circle of adult experiential learning: (1) self-experience (participate in the scenario) or vicarious experience (observe scenario live), (2) reflect on experience (debriefing), (3) abstract conceptualization (debriefing, relate to theoretical material), and (4) active experimentation (future scenarios and use of skills in real cases).

When live transmission is used as an alternative to just watching, the observers can be given special tasks (e.g., look for assigned CRM key points, see Box 7.4) so that they are more engaged in the process. Use of sequences of the scenario recording for debriefing requires additional instructor judgment and high proficiency controlling the replay system.

EXCURSION: DEBRIEFING TECHNIQUES FOR DISCUSSION OF REAL CLINICAL CASES

Techniques of debriefing have also been applied to the analysis of real patient care events. Eppich and colleagues offer a guide to how this can be done in their article *"'Let's talk about it': translating lessons from healthcare simulation to clinical event debriefings and clinical coaching."*[288] Applying the debriefing techniques in short debriefing circles to involved clinical team has also proven quite valuable.[245,276,289-291] Clegg and MacKinnon[292] highlight in their paper *"Strategies for handling the aftermath of intraoperative death"* the need for a debriefing of the OR team after a critical incident in the OR and this concept is in accord with findings of other surveys.[293]

Debriefings after clinical cases can help teams learn.[288,294,295] This is particularly true for crews or action teams with short tenure and changing team membership that have limited time to develop and learn as a team.[296] Here, debriefings offer a useful structure for learning because members may apply the lessons learned from a debriefing of one action team to teamwork of another action team.[296] The advantages of team debriefings include a reduced number of mistakes, higher levels of speaking up and performance, and shorter work duration.[129,296-298]

However, there are barriers to achieving effective debriefings for formative assessment after real cases.[299] For example, teams are typically uncomfortable with explicit communication,[300] they tend to discuss already known instead of new information,[148] and dynamics in organizations foster "undiscussable" topics.[105,301] For example, the various debriefing systems provide useful structures for debriefings after clinical cases, although their particular logistics may have to be adapted to the clinical setting.[302] Unfortunately, most post-clinical event debriefings lack an appropriate setting, a trained debriefing facilitator, and sufficient time. [294] For example, after a cardiac arrest, (1) when resuscitation is successful many of the team members come from the ICU, so they will be busy transporting the patient or otherwise caring for them; or (2) whether or not the event was clinically successful, team members may well have been called away from important activities that need their attention, severely limiting their ability to debrief.

EXCURSION: DEBRIEFING TECHNIQUES FOR MORBIDITY AND MORTALITY CONFERENCES

Much of the philosophy and technique of debriefing applies to discussions of real cases such as morbidity and mortality (M&M) conferences. Both should be about exploring how and why things happened the way they did as opposed to the all-too-common emphasis on who was to blame. Both debriefing and M&M should aim not only to be educational for those participating but also to suggest ways to prevent or mitigate problems in the future, especially by correcting systems issues. Overall, both aim to be constructive, not destructive.

However, both debriefing and M&M conferences face the problem of "hindsight bias" (see also chapter 6). After an event it is often clear what the problem was and how it could have been avoided or best treated, making the original clinicians look foolish. Hindsight bias is very hard to avoid but effort should be made to analyze events from the standpoint of the professionals on the spot in terms of the information they had available at a given moment. Gaba sometimes will explicitly say, *"unfortunately our crystal ball for seeing the future was not operating that day."* Decisions that seem foolish in hindsight will often become totally understandable from this viewpoint.

Another common ground rule is to talk only about observable behaviors—the performance—not about individuals, personality, attitudes, assumptions, or interferences. If someone involved decides to disclose internal thoughts this can then become a topic of discussion. Using such philosophy and technique has a better chance of finding correctable systems issues, fostering a culture of safety, and making personnel comfortable in reporting and discussing problematic cases for the benefit of future patients.

DEBRIEFING IN DIFFERENT CULTURES

While debriefing is widely recognized as an important part of simulation-based training, how it unfolds in practice depends on various contextual considerations. Many of the debriefing models stem from North America and Europe—what might be called the Western cultures. Arguably, the whole idea of debriefing—verbal reflective discussions of actions—might be seen as a Western idea. With simulation spreading more around the world, different national cultures, traditions, habits, and patterns of interpretations become more relevant.[303] The relationship between the learner and the instructor will be influenced by the general customs about how people of different hierarchy levels interact with each other. A recent study, based on interviews with experienced simulation instructors in 28 different countries, showed a strong relation between "power distance" of countries and specific patterns of behavior during the debriefing. The higher the power distance, the more important is the debriefer, the more closed questions are used, and the more difficult it is for participants to discuss issues of non-technical skills and speaking-up.

Qualification and Certification of Simulation Instructors

It has been nearly 30 years since the first major wave of simulation in anesthesiology and other domains began. Over this time a variety of questions have surfaced, in general and at each institution, about how to create and sustain a cadre of simulation instructors. These include: (1) Do simulation instructors need special training? (2) Do they need continuous training after their primary training and if so how much and how often? (3) Do they need to be officially (re-) certified periodically? (4) How can the quality of an instructor be measured or differentiated? This section addresses these questions.

TASKS OF SIMULATION INSTRUCTORS—LEARNING OBJECTIVES FOR SIMULATION INSTRUCTOR COURSES

Sometimes, simulation teaching is completely analogous to bedside teaching, only with a simulated patient, and all the same skills apply. For other uses of simulation new skills may be needed,[112,272,299,304] especially for simulation activity that involves: (1) complex realistic scenarios, (2) with multiple personnel in crews and teams, (3) conducting debriefings in small groups (with or without video), (4) with a focus on human factors and CRM principles and feasible countermeasures. It is widely thought that the quality of the instructors is *the* essential element for any simulation training course, and for complex activities their competence as debriefers is the primary aspect of quality.

Most clinical educators do not necessarily have the skills most needed to be a fully capable simulation instructor. The key tasks include:

- Create relevant, plausible, meaningful clinical scenarios with the necessary realism to reach the intended learning goals (although some instructors who are excellent debriefers leave the design of scenarios to their colleagues).
- Establish an engaging learning context.[121]
- Brief/familiarize simulation participants about the simulator and the unfamiliar simulation environment.[121,299]
- Conduct (complex) clinical scenarios with the need for simultaneous control of (1) the simulator, (2) the simulation environment (i.e., in-scenario information,[261] etc.), (3) the simulation personnel (co-instructors, role-players, simulation technicians, etc.), and (4) the real-time adjustment of scenarios to offer optimal learning for all participants.
- Provide a structured post-scenario debriefing and feedback stimulating self-reflection, facilitating peer-discussion, creating deep and sustainable learning, and promoting transfer lessons to the real world.
- Act on adult learning principles, balancing facilitation and instruction during debriefing (i.e., Kolb's experimental learning cycle, see Fig. 7.20).
- Handle, as necessary, group dynamics as well as individual sensitivities during the training and the debriefing.[272]
- Use recorded audio and video strategically to facilitate debriefing (and/or for feedback especially about technical or procedural skills).
- Teach about crew resource management (CRM) decision making, situation awareness, task and team management, communication, and professionalism in addition to the transfer of medical knowledge.
- Highlight system optimization based on system theory principles of patient safety.

EDUCATION, TRAINING, AND CONTINUOUS DEVELOPMENT OF SIMULATION INSTRUCTORS

Instructor Education and Training

As described by Fanning and Gaba,[238] unlike a traditional teacher, the facilitators can position themselves not as an authority or expert, but rather as a peer and co-learner. Oftentimes, especially for experienced medical teachers,

BOX 7.7 Learning Objectives for Crisis Resource Management–Oriented Simulation Instructor Courses

- Understand how it feels to be a participant in a simulation scenario
- Understand how it feels to be debriefed in a group while others are watching or while seeing oneself on video
- Understand the interdependent influences of the different course phases ("anatomy of a simulation course," see Fig. 7.18) and apply this knowledge to a simulation exercise or course
- Reflect on the changing instructional styles that can be applicable to simulation courses (instruction versus facilitation)
- Understand basic concepts of human factors, crisis resource management (CRM), systems theory, and organizational safety (see Chapter 6)
- Be able to detect, explain, and discuss CRM key points during the debriefing of scenarios
- If using video sequences, use recorded video clips of scenarios well, and select the most relevant portions for replay and discussion
- Be able to conduct a structured debriefing and facilitate a debriefing in a nonjudgmental atmosphere with appropriate boundaries
- Understand how to manage the individual sensitivities and group dynamics of participants during debriefing
- Instead of discussing "who" made "what" "mistake," be able to focus debriefing on the analysis of "what happened," "why did it happen the way it did," "what lessons can be learned," and "how to apply these lessons to real patient care"
- Create a well-designed scenario with learning objectives appropriate for the population

Modified from the learning objectives of instructor courses by Gaba, Rall, and Dieckmann.

the most difficult task in learning this teaching approach is to stop lecturing and start listening and facilitating. At the same time, providing honest critique while holding the learner in high regard—what the authors call "critiquing the *performance* not the *performer*"—seems particularly challenging.[106,304] This is, among other things, why simulation-based educators usually need special education and training. Box 7.7 presents an example of learning objectives for an instructor training course.

Gaba, Howard, and Williams from Veterans Affairs Palo Alto Health Care System /Stanford School of Medicine (VAPAHCS/SU) pioneered CRM-oriented simulation instructor training in 1992, taking their homemade simulation system to Boston for 3 months and teaching approximately a dozen faculty of the Harvard Hospitals anesthesiology programs how to conduct ACRM courses. A few years later a consortium of the Veterans Affairs Palo Alto/Stanford (VAPAHCS/SU), the Boston Anesthesia Simulation Center (the forerunner to the Center for Medical Simulation), and the University of Toronto Sunnybrook Simulation Center created a formal instructor course, spreading the ideas and format of CRM simulation instructor training around the world. Rall has run instructor courses in cooperation with Dieckmann for more than 3000 international participants. Many institutions now offer different instructor courses nationally and internationally (ranging from 2 to 6 days in length, depending on the course and its scope). For further information about such courses the reader is referred to the simulation societies such as SSH or SESAM, or Internet searches targeting well-known simulation centers. In addition, shorter introductory courses on instructor skills are offered every year at the international health care simulation meetings (e.g., SSH's IMSH conference, or the SESAM annual meeting); many workshops at these meetings cover topics such as debriefing, instructor training, and CRM training.

Continuous Faculty Development

Recent research demonstrates the variety of challenges simulation educators perceive when conducting simulation-based training sessions.[272,304] For example, debriefings can include difficult situations such as learners who are unusually quiet, disengaged, or overwhelmed by emotions.[272] Faculty development is important to prepare simulation educators to design and conduct meaningful and respectful training sessions while anticipating potential problems, intervene proactively, and when necessary manage them with good sense and grace.[272,305] Since debriefings are considered particularly challenging, special emphasis is given to continuously improving these skills.[106,306-308]

Reflection can help simulation faculty identify how to improve their debriefing skills.[304] Observation of master debriefers, interactive learning experiences, practice, feedback by peers and experts, and mentoring can foster such improvement.[309-311]

Valid and reliable tools such as the Debriefing Assessment for Simulation in Healthcare (DASH)[307] and Objective Structured Assessment of Debriefing (OSAD)[312] can be used to monitor debriefing quality and provide data for feedback conversations for faculty development. DASH is available in a variety of languages (to date, English, German, French, Japanese, Spanish; https://harvardmedsim.org/debriefing-assessment-for-simulation-in-healthcare-dash/). DASH consists of six rating elements: (1) setting the stage for an engaging learning environment, (2) maintaining an engaging context for learning, (3) structuring the debriefing in an organized way, (4) provoking an in-depth discussion which allows for reflection, (5) identifying performance gaps and their reasons, and (6) helping to see how to improve or sustain good performance. The OSAD consists of eight categories: (1) approach, (2) environment, (3) engagement, (4) reaction, (5) reflection, (6) analysis, (7) diagnosis, and (8) application. Both tools can be applied from various perspectives (i.e., learners, colleagues, educators) which allow for a multifaceted view on debriefing quality.[313]

CERTIFICATION OF SIMULATION INSTRUCTORS

Since being a simulation instructor often requires special skills it is almost universally true that only a small fraction of an institution's faculty or staff are involved in this. For very long-standing simulation groups and centers, informal internal mechanisms have often been used to select and approve instructors. For the bulk of simulation groups and centers there has long been a desire for some formal professional recognition of who is qualified to develop, conduct, and/or debrief health care simulations which has led to different models of certification of qualified individuals. One model is that of the Academy of Medical Educators (AoME),[314] a UK-based organization of educators of medical, dental, or veterinary professionals, for which membership requires satisfying certain levels of achievement in the following five professional standard domains:

- Designing and planning learning
- Teaching and facilitating learning
- Assessment of learning
- Educational research and scholarship
- Educational management and leadership

For each domain, three levels are available that allow assessment and documentation of progress of a person. For more information the reader is referred to the AoME website (https://www.medicaleducators.org/).

The SSH offers a model that addresses more of the simulation-specific aspects of the educator role, and is applicable to all personnel, not just "medical" educators. There is a basic and an advanced level of certification. For more information about the certification for Certified Healthcare Simulation Educator (CHSE) and the Certified Healthcare Simulation Educator—Advanced (CHSE-A) the reader is referred to the society's webpage (https://www.ssih.org/Certification). These programs are rather general and do not fully address the details of qualifications applicable to specific courses. SSH certification has been far more popular for nursing personnel than for physicians; this probably accounts for the fact that few simulation instructors in anesthesiology have obtained formal certification. In another approach, while the U.S. ASA Simulation Education Network (SEN) program endorsement process does not yet certify instructors, when considering a site for endorsement it does examine the simulation background of the site's instructors, as well as the process by which each site trains and approves new instructors for their program.

It is likely that the skills and certification needed (if any) for an instructor will vary greatly with the particular course or curriculum being taught. Competence in conducting a video-based CRM debriefing would not be needed, and would not help, to teach specific manual procedures (e.g., airway management or central venous cannulation) using part-task trainers. Some sites use either a formal or informal system of tiered instructor categorization tied to the specific types of courses and roles each individual is capable of conducting. This also provides a defined process for advancement from novice instructor to grand master as experience and special training are acquired.

Accreditation of Simulation Programs, Sites, and Centers

Besides the qualification of the instructors, the physical and organizational infrastructure is important for the quality of simulation in health care. This aspect is discussed under the label of accreditation. The SESAM wrote: *"By seeking accreditation an institution can demonstrate its quality as having been judged and validated by an independent body who is internationally recognized as an opinion leader in the domain of simulation-based education in healthcare."*[315]

Several systems of program approval have emerged, some of them of particular interest to anesthesia professionals.

SESAM provides a model that has two levels of accreditation (www.sesam-web.org/accreditation/). The basic level is done based on the description of the program's work; the expanded level also includes a site visit.

BOX 7.8 **Simulation as Favored Option for Part IV of the U.S. Maintenance of Certification in Anesthesia Program by the American Board of Anesthesiology**

The simulation course must be held at a site endorsed by the Simulation Editorial Board of the American Society of Anesthesiologists, with a curriculum meeting minimum standards. Although not specifying anesthesia crisis resource management (ACRM) directly, the standards for the U.S. Maintenance of Certification in Anesthesia (MOCA) simulation are clearly derived from the ACRM simulation courses that have become common around the world:

- A minimum of 6 h of total course instruction
- Active participation in realistic (mannequin-based) simulation scenarios
- Post-scenario instructor-facilitated peer debriefing
- Management of difficult patient-care scenarios, including at least scenarios involving the following: (1) hemodynamic instability and (2) hypoxemia of any cause, including management of the difficult airway
- An emphasis on teamwork and communication
- All participants have at least one opportunity to be the primary anesthesiologist in charge (i.e., the "hot seat")
- The participant-to-instructor ratio must be no greater than 5:1
- At least one instructor must currently be in the MOCA process

The SSH provides an accreditation program, with separate but related accreditations for core standards plus one or more of the following areas of emphasis: teaching/education; assessment; research; systems integration. For more information, the reader is referred to their webpage (https://www.ssih.org/Accreditation/Full-Accreditation).

The U.S. ASA has a process to endorse anesthesia simulation programs (the ASA chose not to use the term accredit) qualifying them to be members of the ASA's SEN. Centers were originally endorsed for their ability to deliver high-quality CME to ASA members. After reaching agreement with the ABA in 2010, this ASA SEN rapidly transformed into a group of programs capable of conducting the semi-standardized Maintenance of Certification in Anesthesia (MOCA) Simulation Course. The course is a component of Part IV (practice improvement) of the ABA MOCA process. Box 7.8 shows the features of the U.S. Maintenance of Certification in Anesthesia (MOCA) simulation program.

As of November 2018, the ASA had endorsed more than 50 programs, each of which was reviewed and approved by the ASA Simulation Education Editorial Board after completion of a detailed application documenting the capability and experience of their simulation instructors, leadership, facilities, and procedures (for ASA members, see http://www.asahq.org/For-Members/Education-and-Events/Simulation-Education.aspx).

The American College of Surgeons (ACS) has a program of Accredited Education Institutes (AEI) that "*…educate and train practicing surgeons, surgical residents, medical students, and members of the surgical team using simulation-based education.*"[316] Many anesthesia simulation programs, especially those endorsed by the ASA-SEB, have a close collaborative relationship with their institution's ACS-AEI.

Benefits, Effectiveness, and Ecological Validity of Simulation Training

In the era of evidence-based medicine everyone wants to know *"does simulation work?"* and "*what is its cost effectiveness?"* This question has now been answered affirmatively, but only for a selected few circumstances. In fact, it seems clear that for many of the common, but most challenging arenas of health care, these questions may not be answerable for all practical purposes.[317] Some argue that the question of whether simulation works needs to be replaced by questions about *"when," "how,"* and *"under what conditions"* simulation "works," and finally *"how 'works' can be defined"* in a given context. In the following, the benefits of simulation are summarized, and some challenges to answer the above raised questions as well as some key findings in settings in which studies were feasible are reviewed.

BENEFITS

Simulation in health care has some fundamental advantages as a training tool. The following were modified and expanded based on the work of Gaba and DeAnda[177]:

- No risk is posed to a patient despite "hands-on" training.
- Routine clinical situations, emergency situations, and those involving uncommon but serious problems can be presented at will.
- Participants can learn to use actual complex devices, often in the relevant clinical context.
- The same situation can be presented independently to multiple subjects for evaluating individual or group performance.
- Errors can be allowed to occur and play out to their likely conclusion, whereas in a clinical setting they would require immediate intervention by a supervisor.
- To a reasonable degree, the training can be standardized and is reproducible.
- Training can be focused and allows for various forms of feedback or discussion that are difficult to embed into real patient care settings.
- "Clinical time" is under the control of the instructor; boring portions can be skipped or sped up while very difficult segments can use time dilation to allow unfamiliar individuals to have a full chance to grasp and handle the situation.
- Simulation can be stopped and restarted for teaching; time of physiological changes can be expanded or compressed, including "death-control."
- Recording, replay, and critique of performance are facilitated because patient safety or confidentiality is not an issue.

Simulation accelerates skill acquisition, improves skill retention, and reduces the extinction of skills.[26] Simulation has been heavily utilized to address non-technical skills (see Chapter 6) such as communication, teamwork, task management, leadership, situation awareness, and decision making. Those non-technical skills and human-factor-based training approaches are vital to conduct safe patient care, taking into account human performance strengths and weaknesses (see Chapter 6). Nevertheless, as mentioned below, such an arena will be the hardest to ever prove that simulation improves patient outcome.

Despite the many advantages of simulation in health care adverse effects of simulation are possible. A stimulating critical overview of medical education in general was written by Hodges and was provocatively titled "*Medical Education and the maintenance of Incompetence."*[318] The article points out that any type of education runs a risk of creating or maintaining incompetence in certain areas, especially areas that are ignored by the actual educational program. The authors recommend that all simulation instructors be especially cognizant of the risks that Hodges articulates.

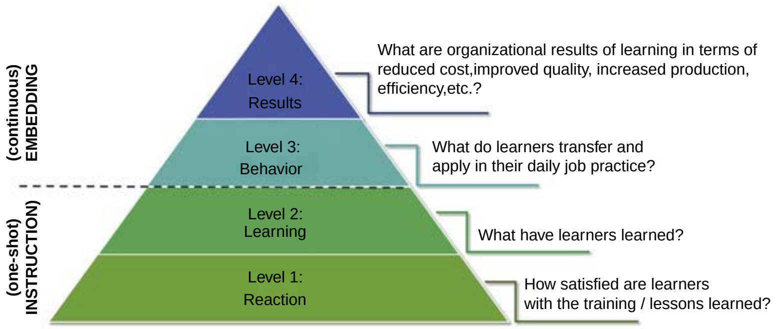
EFFECTIVENESS

Challenge #1: Comparability of simulation research and evaluation of simulation. For the question of whether simulation works and how effective simulation is in regard to different aspects, evaluation concepts need to be defined and a common ground for the comparison of research in simulation needs to be produced. For the evaluation of learning and later performance outcomes, respectively, oftentimes the four-level model of Kirkpatrick as shown in Fig. 7.22 is cited.[319,320]

Another concept used to evaluate simulation is that of translational science—research designed to accelerate movement of results from the laboratory bench to the patient bedside. The concepts of a continuum of research from fundamental science through clinical trials to widespread use in patient care and of potential translational blocks were articulated originally by Sung and colleagues in 2003.[321] From this publication emerged various nomenclatures for the different levels of the research continuum in terms of increasing level of translation, called T Levels.

For education, translational science addresses how results achieved in the educational laboratory (T1) transfer to improved downstream patient care practices (T2) and improved patient and public health (T3).[322] McGaghie[322-324] first adapted the T levels of translational research to the arenas of medical education and simulation in health care, comprising T1, T2, T3, and T3′ (Table 7.5). The most important T levels for simulation interventions are T1: is performance improved when observed during simulation?; T2: does actual clinical behavior change in the workplace?; T3: is there a change in patient outcome?; and to a lesser extent T3′: is it cost-effective?

Based on those two concepts, for research purposes simple outcomes are Kirkpatrick level 1 (reactions of participants) and Kirkpatrick level 2 (change in self-confidence or of knowledge measurable via multiple choice questions). Both Kirkpatrick levels are represented by level T1. Rall et al.[325] later adapted additional T levels mentioned in other sources,[326,327] adding levels of T0, T4, T5, and T6 (see Table 7.5), and categorizing interventions by their intended outcomes. Researchers in simulation are now starting to use this terminology in describing and comparing their research protocols and results.



(continuous) EMBEDDING
(one-shot) INSTRUCTION)
Level 4: Results
Level 3: Behavior
Level 2: Learning
Level 1: Reaction
What are organizational results of learning in terms of reduced cost,improved quality, increased production, efficiency,etc.?
What do learners transfer and apply in their daily job practice?
What have learners learned?
How satisfied are learners with the training / lessons learned?

Fig. 7.22 Kirkpatrick's four-level training evaluation model. The model is composed of four levels: reaction—learning—behavior—and results.

TABLE 7.5 Translational Research Levels of Simulation-Based Training

Level	Description of Study Methodology	Comments/Examples
0	No measurement of learner performance	Questionnaire or multiple-choice test to assess reaction/change in knowledge
1	Performance measured during simulation only	Do participants do better in a subsequent simulation?
2	Performance measured during actual clinical care	Do participants do better in subsequent clinical practice?
3	Measurement of improvement in patient outcome	Do patients of those who had the training fare better?
3′	Measurement of cost of the intervention, the outcome, and the monetary benefit (= measuring "cost effectiveness")	Does intervention yield a net saving of money (with/without improving outcome)?
4	Measurement of dissemination of the intervention to sites beyond trial sites	Has the intervention spread elsewhere successfully?
5	Measurement of adoption of the intervention in regular practice	Has it been widely adopted?
6	Measurement of population health outcome	Has it made an impact on patient population as a whole?

Challenge #2: To define cost-effectiveness, expenses need to be put in context relative to return on investment. In simulation education the focus of evaluations historically has been mostly on qualitative instead of quantitative measures, and the suite of measurements needed to assess learning outcomes and patient outcomes are still in flux. Bukhari and colleagues published a framework for determining the return on investment of simulation-based education in health care.[328] Unfortunately, so far, evaluations that yield economic information about the return on investment are scarce.[329] And the expenses (see later section) vary (high cost to low cost) depending on many choices regarding the setup of the simulation training (see earlier section on "12 Dimensions of Simulation").

At this point, most studies of simulation-based learning are at level T0 or T1. At lower T levels simulation of various sorts has been shown to have small to medium positive effects.[330] A few studies have been at T2 and only a handful at T3 or T3′ patient outcome. Draycott and colleagues[331] showed positive effects of training that included some simulation components on neonatal outcome. Barsuk and colleagues[126] showed a reduction of central line complications and cost-efficacy after implementing simulation-based training on central venous cannulation. A series of studies from Tanzania shows that positive effects for patients is not necessarily related to the use of high-end simulation equipment.[38,332] Van de Ven and associates[333] concluded in their study that multiprofessional team training for obstetric emergencies in a medical simulation center is cost-effective in a scenario where repetition training sessions are performed on-site. Levels T4 and T5 can be considered implementation science, but few studies of simulation implementation have been performed.

Simulation researchers are encouraged to move toward studies at higher levels of translational research whenever possible. Admittedly, the cost and complexity of studies also rises non-linearly as one climbs the "T ladder." Since many applications of simulation in anesthesiology especially focus on preparing anesthesia professionals to prevent and manage uncommon but serious adverse events more effectively, the rarity of such events and the many confounding variables that affect patient outcome will make intervention studies very difficult to perform.[317]

These studies would per force need to be large, long, and complicated. To date, almost all studies have been too short and too unsystematic, with weak interventions and without adequate control of confounding variables. Unlike many types of clinical trials, which are funded by the pharmaceutical industry—which is willing to invest heavily even in complex trials because of the high direct payoff when a blockbuster drug is found—simulation interventions have no equivalent funding sources. Obtaining level 1A evidence—with multiple randomized controlled trials—of simulation's impact on patient outcome may well take studies of thousands to hundreds of thousands of patients, cared for by hundreds or thousands of clinicians, with simulation interventions that are powerful, comprehensive, sustained, and linked to performance assessment (and remediation) of individual clinicians. As yet, no agency or commercial firm is willing to fund these kinds of large, long, and complex studies.[317] And neither aviation nor nuclear power have assembled "level 1A" evidence that simulation saves airplanes, power plants, or lives. It is unlikely that aviation would ever attempt randomized trials and such studies would be nearly impossible, if not unethical.

Challenge #3: High-fidelity patient simulations can be effective and cost-effective, but work will be educationally effective only, if they meet certain criteria. Flanagan and associates provided a thorough review of the literature on the efficacy of simulation-based training for learning and assessment.[334] They concluded that "simulation makes a valuable contribution to learning for students, trainees, and clinicians. It enables learning of both routine and non-routine procedures and management of patients." In one study the effect between hours of simulation practice and learning outcomes equaled a dose-response relationship.[198]

Similarly to Flanagan, Cook and colleagues[330] concluded in their comparative review that simulation was typically more expensive but also more effective. In their summary, in comparison with other instructional methods, technology-enhanced simulation was associated with small to moderate positive effects. In another comparative review by Cook et al.[335] in which technology-enhanced simulation training in health professions education was compared to "usual practice," simulation was consistently associated with large effects for outcomes of knowledge, skills, and behaviors, and moderate effects for patient-related outcomes. Such findings were confirmed by Lorello et al.[15] in their most recent review; they and other authors[198,334] pointed to the heterogeneity of the studies, the sometimes limited robustness of their methods, and the occasional lack of a suitable control group.

A Best Evidence in Medical Education review by Issenberg and colleagues concluded that high-fidelity medical simulations are educationally effective, but only if the following conditions are met[198]:

- Educational feedback is provided.
- Repetitive practice is used or is allowed.
- Simulation is integrated sensibly into the standard curriculum.
- The range of task difficulty can be adapted to the level of the learner.

Challenge #4: Limitations of research on simulation effectiveness. Even the strongest of results come with caveats. First, it can be difficult to isolate the effects of simulation in the evaluation. In many cases simulation is only a part of a larger bundle of interventions, or concurrent with improvements in the clinical field as a whole ("secular change" as statisticians say). Second, as in the case of central venous cannulation, sometimes the clinical activity is circumscribed, the outcomes are relatively common, there is already ongoing surveillance for them, the relationship of the activity to negative outcomes is well-understood, and the intervention is itself narrow, proving an effect on patient outcome is easy. But for many arenas, especially for the anesthesia professional's management of unexpected adverse situations, the events are relatively rare; there is weak surveillance for negative outcomes, as well as many confounds between anesthesia professionals' actions and the final outcome; and the simulation interventions are complex. Proving an outcome improvement is difficult in such settings and likely would require long, complex trials involving many tens or hundreds of thousands of patients, thousands of clinicians, and a very long time horizon, as mentioned above. Further, it is unrealistic to expect that a single set of training can change complex behaviors and actions or affect patient outcome especially when there is little reinforcement in or linkage to performance assessment in actual clinical practice.

Challenge #5: Assessing the impact of simulation in health care as if it was a pharmaceutical. The assessment of the impact of simulation to date can be seen using the following analogy to drug development and testing that was introduced by Weinger[336] and expanded to address the related policy issues by Gaba.[317] Suppose one wished to test whether a purported antihypertensive drug actually succeeded in reducing blood pressure in patients and, more importantly, whether it reduced the occurrence of adverse cardiovascular events, such as myocardial infarction and stroke. Imagine then that one proceeds as follows: administer a relatively small dose of this drug only a few times per year. Acknowledge variable compliance in taking even these few doses of drug. Immerse all subjects in an environment full of stress and other factors predisposing to cardiovascular events. Use only a few patients, and follow them for a very short time.

Would anyone wonder if no significant effect was found even for a drug otherwise known to be effective? Simulation in health care has so far been tested in this way: very small, short-term studies of infrequent (often short) simulation sessions, whose lessons are not fully reinforced in real clinical environments full of production pressure and stress. In truth, the question is not "*Does one run through a simulation course make a practitioner better?*" To follow the lead of other industries of intrinsic hazard, such as commercial aviation or nuclear power production, the question is "*What is the impact on health care as an industry adopting a comprehensive integrated strategy of intensive simulation-based training and continued performance assessment of clinical personnel, over a long period of time?*" This is the approach in aviation, in which no matter how senior and how experienced pilots are, they still undergo training and assessment in simulation every year, for the entirety of their careers.

It seems unlikely that pilots would forgo simulation training and assessment when their own lives are on the line. For another thing, the public has come to expect a regulatory safety floor imposed by the government to ensure the competence of pilots. The regulator is unlikely to forgo its requirement for mandatory training and testing of pilots. If such requirements continue, there may be only two options: conduct these exercises in real airplanes, with the attendant costs (e.g., fuel) and risks; or conduct them using simulation. With health care heading in that direction,[92,222,226,245,337,338] one may be able to assess the impact of more effective simulation programs, although one may lose a control group that has never experienced simulation.

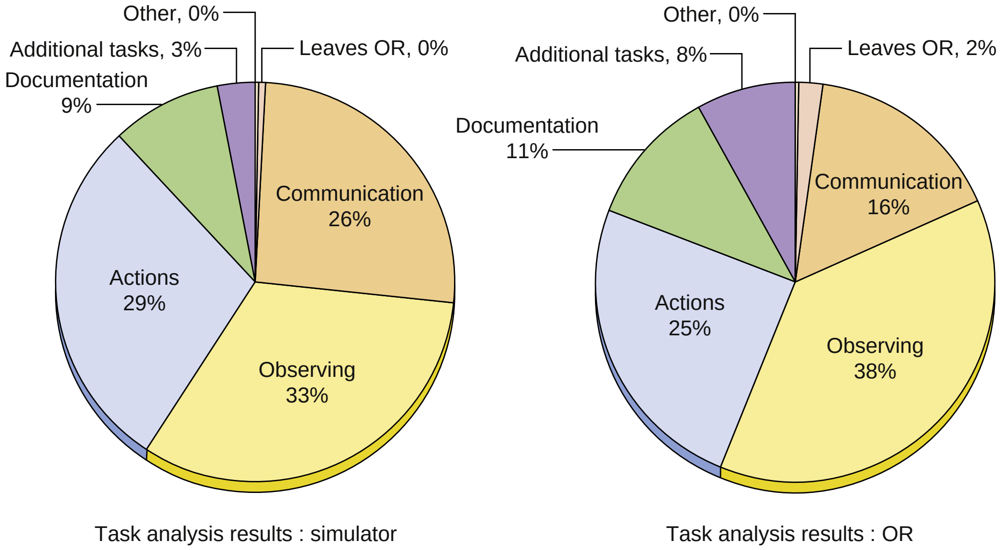


Fig. 7.23 Ecological validity of simulation versus the operating room *(OR)*. For study purposes[160], the same anesthesiologists were observed in the OR and in the simulation environment with full enactment of the OR personnel, surgical team, and anesthesia nurse. Even though the two settings have some interesting differences, the overall ecologic validity of the simulation is good. (*Courtesy of T. Manser, ETH Zurich, and University Hospital, Tübingen, Germany.*)

Other industries have a career-long set of simulation interventions that are considered to have a cumulative effect on ability. Social psychologists Helmreich and Foushee, two of the main architects of CRM training, wrote: *"Data indicate that even intensive initial CRM training constitutes only an awareness phase and introduction to the concepts, and that continuing reinforcement is essential to produce long-term changes in human factors practice."*[339] Similarly, United Airlines states in its CRM manual: *"Command/Leadership/Resource management [United's terminology for CRM] cannot be a one-shot approach. It has to be a coordinated long range program. It must therefore be an integral part of the entire training effort: new hire training, transition and upgrade programs, and recurrent training."*[340]

ECOLOGICAL VALIDITY OF PATIENT SIMULATION: IS THERE TRANSFERABILITY TO THE REAL WORLD?

When trying to translate behavior of professionals in the simulation to the behavior professionals might show during real clinical cases, one of the questions raised is the one about whether simulation can engage trainees the same way a real clinical case would. Simplified, in psychological science this is referred to as ecological validity. If actions and behavior in the simulation resemble the actions and behaviors in real-world clinical environments, it is likely that the results of research conducted in a simulation setting or lessons learned in a simulation training will be transferable to the context of actual patient care.

Patient simulation: A valid representation of the clinical reality? The question whether full-scale simulations are a valid representation of the real work environment tasks (e.g., tasks of an anesthetist in the OR, etc.) was investigated by an interdisciplinary research group in Tübingen, Germany and Zurich, Switzerland.[160] Each of the six anesthesiologists participating in the study was observed during two clinical cases and during three comparable simulator cases (one routine and two involving critical incidents). Analysis of the study showed good comparability of the different action categories as shown in Fig. 7.23. The interpretation of the group was that overall comparability between the operating room and the simulator setting is good, thereby indicating high validity for simulators in anesthesia.

Another more recent study by Weller and associates [341] examined the validity of the simulated environment with the question of whether anesthesia professionals show similar verbal communication patterns during a simulated and a real case. Seventeen anesthetists were observed via videorecordings during real cases and two simulated cases. Confirming the findings mentioned by the group in Tübingen and Zurich, the authors of the publication found no significant differences in communication patterns in the OR and the routine simulations. The participants themselves rated communication as realistic and considered their communications occurred with a similar frequency in the simulations as in comparable cases in the OR.

Those findings support the validity of the simulation environment and its value for transferable training and provide further objective confirmation of the favorable subjective impressions of realistic simulation scenarios by anesthesiologists of varying levels of experience.[65,68,69,178,179,181,342] Therefore, the evaluations presented in this chapter suggest that simulator-based training is a powerful technique that novice and experienced anesthesiologists believe to be highly beneficial, and that participants and instructors alike believe may improve clinical performance. As the developers of Sim One[175] pointed out, when simulation provides an opportunity to teach material that cannot be taught in another way, as for the systematic instruction of anesthesiologists in handling severe critical events such as cardiac arrest, anaphylaxis, or malignant hyperthermia, there is nothing with which to compare the simulator.

Simulation replacing clinical hours or case numbers during training? Because simulation offers a valid representation of real health care settings and behaviors, and also offers several advantages, in settings for which a certain number of clinical hours or patient cases are a prerequisite for certification or credentialing, simulations are sometimes allowed to replace some portion of the requirement. This is true in some states in Germany for prehospital emergency physicians (and possibly soon [pilot project] for paramedics) who are allowed to cover 25 of 50 mandatory prehospital cases within a specific 3-day simulation program.

For nursing, in the United States, 22 states allow some degree of simulation replacement of clinical hours required for final licensure as a registered nurse; the number or percentage of hours varies widely as does the specificity of the regulation and whether there are any standards for the intensity or quality of the simulation activities (see https://www.inacsl.org/sim-regulations/). A large and complex study of educational outcome (not patient outcome) provided evidence to support these practices,[343] although from Gaba's view there were some limitations concerning study methodology and the generalizability of the results.

Differences between simulated and real-world cases. Even though the mentioned studies showed high ecological validity of patient simulation, some differences between simulation and real patient care are inherent to simulation and need to be taken into account when debriefing and assessing the performance during a simulated scenario. Based on the findings of Manser and colleagues[160] variations were mostly the result of organizational factors (e.g., fewer additional tasks required in the simulator). At the same time, as described in the literature,[75] subjects (1) eventually become hypervigilant realizing that they are in a simulation, being more attentive or even doing more than they usually do (e.g., participants neglect documentation in the simulation while waiting for a disaster to happen, or scan the patient's documents at length before starting a simulated case so as not to miss an important hidden hint, or jump too quickly on signs of possible trouble); (2) conversely, will not or cannot take the situation serious because it is not a "real patient" and thus do not perform all the actions as they would for a real patient (e.g., acting sloppy, showing cavalier behavior, acting like it is a game).

Careful and creative scenario design and scenario conduct as well as proper introductory briefings may mitigate some of those effects (see earlier sections on those topics).[273]

Cost of Patient Simulation and Simulation Centers

COST OF PATIENT SIMULATION

An important question concerning simulator-based training in anesthesia is its cost effectiveness. This complicated question has two independent components. The first pertains to the impact and benefit of the training on the performance abilities of participants and patient outcome (discussed above), and the second is the cost to achieve that impact.

Although measuring the cost of simulation-based training depends on many factors, the cost may still be more easily estimated than is the impact of the training. Factors affecting the cost include:

- The type (or spectrum of types) of training involved
- The target populations for the training
- And perhaps most importantly, a variety of aspects of the organizational and financial structures and processes of the institution

The cost of simulation hardware and software varies greatly (and much simulation can be done with little to no technology). Screen-only simulators cost very little (a few hundred dollars), whereas the equivalent cost of a complete mannequin-based simulator or VR system is much higher. The price of a commercial mannequin-based simulator ranges from approximately $25,000 for intermediate-capability simulators to more than $150,000, depending on features; only the manufacturers can provide detailed information. This cost does not include any relevant clinical equipment (which, say, for an anesthesia machine is very high) and also of course the building and maintenance of a center's space.[344] Even these large expenditures do not dominate in the operational cost equation, however, because the construction cost is often borne by the institution itself, capital equipment can sometimes be donated or acquired used, and in general is amortized over a relatively long useful life, with appropriate provisions for service and upgrades.

The overall dominant cost for operating a center is likely to be the salary and benefits of its permanent personnel and the effort of expert instructors (which is typically borne directly or indirectly by their clinical department). These costs vary considerably across the spectrum of simulation activities and institutional arrangements. Usually an expert must oversee the curriculum (which may or may not impose direct costs), but the type of training and the target population will determine the amount of expert instruction required. A single faculty member can review the summaries of exercises performed by residents on a screen-based simulator in a few hours per resident per year. Non-physician instructors may be suitable for some task training or for drill and practice sessions. A single instructor can use the simulator to show pulmonary or cardiovascular physiology to a whole class of medical students. For training novice residents in basic anesthesia skills, it may be possible to have senior residents or fellows conduct the sessions at a low marginal cost. For training experienced residents and practitioners in complex material, such as the handling of critical events, it is likely no substitute expert instructors exist. The cost of expert instruction depends on the organizational arrangements of the institution. In a teaching institution where faculty members all have at least some time allocated for teaching or scholarly activities, some faculty may choose to fulfill this requirement by simulation-based teaching or scholarship. When further instructor effort is needed, payment—by the department or the center—for clinical release time may be needed.

Another organizational cost factor relates to providing access to participants for what can be complex, exhausting, and lengthy training sessions. Removing clinical personnel from revenue-producing work for training purposes is expensive. If simulation training could allow them to work more safely and efficiently, the benefit could outweigh the cost. Some research indicates that simulation team training can improve job satisfaction and effectiveness of routine care, as well as contributing to reduced illness leave and job fluctuations.[345] Some residency programs provide protected time for education of residents (e.g., one half day per week). In such cases, residents should already be available for simulation, but it might make faculty time even more scarce. In Australia and Germany, CME requirements are expressed in terms of points to be accrued.

Without question, simulation-based training is more costly than exhorting learners to read or putting them in a room with a lecturer. But when regarding credits for continuous medical education (CME), reading a short article and answering a handful of questions can only generate 1 hour of credit—or as in Australia and Germany only a small amount of CME points, as can sitting through a lecture. Simulation training is generally much more interactive and much more intensive than other activities and therefore professionals earn more credits or points, which may make simulation-based CME financially competitive relative to simpler methods.

Simulation-based training allows a host of issues to be addressed that cannot be easily tackled in other ways. It is the belief of the authors—one that has been borne out by programs "voting with their feet" since the 1990s—that if simulator-based training is deemed to be desirable, innovative changes in the organization will evolve to allow it to occur.

But other emerging aspects also make patient simulation a beneficial tool for addressing future organizations' needs. At the Harvard University hospitals, for example, the captive insurer, Harvard Risk Management Foundation, has taken unprecedented steps to link simulation-based continuous medical education training to discounts for medical malpractice premium rates for experienced clinicians in anesthesia and in obstetrics (J. Cooper, personal communication, 2005). This forward-thinking program is now being adopted by other malpractice carriers. In some jurisdictions, risk managers have chosen to invest directly in simulation activities at their institution, rather than to use the premium discount approach.

COST OF SIMULATION CENTERS

The cost varies greatly depending on the scope of the facility and its programs, the nature of the target populations, and the extent of use by the different possible stakeholder groups. How the costs are allocated to different elements of an institution or consortium is equally complicated and depends highly on local conditions. No one formula for success exists. In some models, the center is wholly responsible for its own costs but is completely free to generate and retain revenue. At the other extreme is a model whereby the host institution bears all costs of operating a central core facility, but it collects any and all revenues and may even tax components of the institution (e.g., departments) to offset the costs. Perhaps most common are mixed models in which the central authority bears the costs of initial construction and outfitting (often funded by philanthropy) and some portion of the ongoing infrastructure (simulation operations personnel, capital refurbishment, utilities), and each user (e.g., department) is responsible for providing instructors and paying for the marginal costs of any specific course or application. To date, few, if any, centers truly generate a profit, but many sites have successfully garnered external funds to offset some of the costs of training their own key target populations.

Using Simulation for Assessment of Clinical Performance

Although the dominant use of simulation is for education and training, the first simulators (both Sim One[175] and CASE[177]) were created to be research tools to assess and understand the performance of clinicians. Such assessment could address routine work in clinical environments[115,134,136,346,347] as well as performance when responding to critical events.[64,68]

Note: the terms "assessment" and "evaluation" are often used interchangeably even though they have slightly different meanings, so the authors chose to do so in this chapter, too.

For further information on the assessment of clinical performance that is related to the topics of human performance and patient safety the reader is referred to Chapter 6, where less simulation-related aspects of this topic are covered in more detail.

Performance can be divided into two components: (a) medical or technical performance, which is the appropriateness and thoroughness of the medical and technical response to the critical event; and (b) behavioral or nontechnical[348] performance, which is the appropriate use of sound crisis management behaviors (e.g., leadership, communication, distribution of workload, decision making, etc.) [24,349] (see Chapter 6).

There are a number of potential frameworks that can be referenced when defining clinical and nonclinical competencies for the performance assessment of health care professionals. In different countries, different frameworks are used to describe anesthesiologist's competencies, which provide the ground for assessment measures. Many countries build on the CanMed roles[350] (Canadian Medical Education Directives for Specialists) that describe seven roles for the competent physicians. Those roles are: medical expert, communicator, collaborator, leader/manager, health advocate, scholar, and professional. Other countries build on the six ACGME (Accreditation Council for Graduate Medical Education) core competencies, which include patient care, medical knowledge, practice-based learning and improvement, interpersonal and communication skills, professionalism, and systems-based practice. [102]

Assessment of medical, technical, and non-technical responses in simulation settings has resulted in a variety of tools for assessment and evaluation as suggested by different authors.[64,69,89-93,97,99,101,136,342,349,351-354]

For assessing the non-technical skills of anesthesiologists many investigators use the Anaesthesia Non-Technical Skills (ANTS) system.[91,353] In recent years, the early ANTS evaluation system was adapted to different countries, and modified for different cultures[351] and health care specialties.[355] However, there are other tools for measuring non-technical skills of anesthesia professionals. Of particular note is a rubric developed by Weinger, Gaba, and colleagues[64,356] which is simpler than ANTS but of equivalent capability.

BENEFITS OF SIMULATION-BASED PERFORMANCE ASSESSMENT

Because the nature and cause of a simulated critical incident is known, one can construct in advance a list of appropriate technical activities.[357] Relative weighting of the importance of the different activities can be applied to reflect the fact that different activities, even if appropriate, differ in their importance. This weighting can be done either in advance of data collection, or post hoc (but in an appropriately blinded fashion). For example, when assessing medical or technical performance in managing malignant hyperthermia, termination of the trigger agent and administration of intravenous dantrolene would be highly important, indeed essential, items. Cooling measures, hyperventilation, and bicarbonate therapy would be among many appropriate (but less critical) responses. One can predict in advance specific technical errors to look out for. For example, for malignant hyperthermia management, these could include diluting dantrolene with the wrong diluent or an insufficient quantity of diluent.

Can the clinical outcome of a simulation predict how a real patient would have fared given the same care, and can this outcome be used in assessment? When watching a simulation scenario play out it seems tempting to think that the outcome of the patient—whether calculated by an underlying mathematical model of physiology (for a few simulators) or based on apparent adherence to patient care guidelines—can be the primary determinant of an individual assessment or a definitive prediction of what outcome a real patient would have had. Such a temptation is largely dangerous. Perhaps at the extremes of what transpired the apparent outcome could be reliable. If a patient is portrayed in ventricular fibrillation and nothing is done it is certain that they will die. If a healthy patient with substantial neuromuscular blockade receiving a FiO_2 of 50% oxygen is suddenly not ventilated for 30 seconds it is nearly certain that they will be fine. In between such extremes the exact outcome is very hard to predict. There will be isolated situations in which a mathematical model can predict certain physiologic variables, but the influence of those on other variables may be unknown. Why do some patients suffer an arrhythmia if their blood pressure falls below, say, systolic pressure of 50, 60, or 70 torr for a certain amount of time whereas others tolerate it fine? Why does one patient have return of spontaneous circulation after electric countershock applied at the same interval after dysrhythmia onset and another does not? Perfect decision making in resuscitation of a real patient cannot guarantee that electric countershock would successfully restore a normal cardiac rhythm. For the foreseeable future, any credible performance measurement technique must involve subjective judgments by clinical experts about the care process rather than about the calculated or presumed outcome.

PITFALLS OF SIMULATION-BASED PERFORMANCE ASSESSMENT

Technical versus nontechnical (CRM) skills. As indicated in previous sections, it is feasible (if difficult) to assess a technical response to specific events and generic nontechnical behaviors (CRM). For which kinds of assessments is it appropriate to measure only technical performance, only nontechnical performance, or some combination of the two?

Number of scenarios. How many different scenarios are needed to achieve robust performance assessment of individuals in all relevant aspects (technical and nontechnical) of patient care? The literature suggests that the variability of individual performance across different scenarios is high, in fact greater than the variability across raters. If simulation is to be used to assess an individual a large number of scenarios would need to be conducted for each person. Having a larger number of scenarios is more effective in improving the reliability of ratings than is having a larger number of raters.[64,237,358]

Rating individuals versus rating crews or teams. Anesthesiologists work as individuals and in crews and teams with other anesthesiologists and with surgeons, nurses, technicians, and others. Should the performance of individuals working alone be assessed? Should anesthesiologists be able to call for and use help in solving problems? If so, can one still rate the individual when working with a team?

Performance fluctuation. How can performance that fluctuates substantially over time (i.e., during a simulation scenario) be aggregated into a single rating? This issue was recognized by Gaba and colleagues as a major apparent source of interrater disagreement.[349] It is not addressed by any current rating system.[91,359] One option is to conduct moment-by-moment rating to yield a high-resolution time series of the varying performance. A variety of mathematical techniques could then be applied to the time series to yield appropriate measures of aggregate performance and variation.

Criterion thresholds. What level of performance should be set as criterion thresholds for different purposes? Can benchmarks of performance be established by truly expert clinicians (recognizing that years of experience and hierarchic rank are not surrogates for expertise or skill)? Similarly, how does the rating system deal with single actions or behaviors that were lethal or harmful in the presence of otherwise good performance? If used for formative assessment, a rating system should indicate the successes of the examinee and the failures. If used for summative or high-stakes assessment, however, it may be critical to ensure that the examinee who risks harming a simulated patient cannot outscore another examinee whose overall performance is less strong but who at least did not endanger the patient. Not performing chest compressions in a cardiac arrest situation would be such criterion for exclusion.

Appropriate statistical analysis of validity, interrater reliability, and reproducibility of these assessments. Various statistical tests and approaches have been used to evaluate these characteristics. The data on performance show various levels of interrater variance and high interindividual (and inter-team) variability.[68,69,181,342,349,360] As detailed by Gaba and colleagues,[349] some interrater reliability statistics are more stringent than others, especially in terms of the nature of the "by chance" benchmark. No firm consensus has been reached regarding which tests are most appropriate to answer key questions about simulation-based performance assessment. Some of the rating systems (including ANTS) have used less stringent tests of interrater reliability. Generalizability theory[361] offers a set of statistical techniques to sort out the impact of scenario, subject, rater, number of scenarios, and other facets on such assessments. This technique specifies how comparisons can be made against reference performance levels or as relative comparisons between subjects without a fixed benchmark.

Although simulation should provide a useful window on performance assessment, it remains challenging to develop widely accepted performance measures of anesthesiologists' skills,[362] even if the simulator is used as a tool to present standardized scenarios.[363] Klemola and Norros[364] published a newer way of looking at performance that involves anesthesiologists' habit of actions. These authors distinguished between reactive habits (conservative, self-contained, reluctant to construct subjective evaluations) and interpretative habits (creative, interactive, continuous integrative reasoning). They showed that many issues must be considered when discussing the best method of education and evaluation. Additional issues include defining and assessing professional competence.

USING SIMULATION FOR THE EVALUATION AND TESTING OF ANESTHESIA PROFESSIONALS

The use of simulation as a tool for performance assessment has presumed advantages: scenarios are known, errors can be allowed to occur and play out, and intensive recording and archiving of performance is possible. Simulation provides a unique window on performance that is prospective and about challenging situations, whereas routine observation of real work is prospective but most commonly only sees less challenging situations, and case reports about performance may be of tough cases but are often incomplete and hindsight-based.[365] Scoring or certifying competence by using the simulator is more problematic than using the simulator as a teaching tool, however. Anesthesiologists have long discussed the possibility of using the simulator as a tool for examinations, either for graduation from a residency or for ABA certification. In Israel, a simulation examination has become part of the board certification process.[95]

Despite these difficulties, the use of anesthesia simulation to assist in evaluating performance is likely to increase in the future. Even though simulation is currently used for some high-stakes examinations, the challenges remain the same: (1) It requires independent evaluation of the simulation scenarios and assessment of the predictive power of the subjective judgments made by experts scoring the examinee. (2) There is a lack of any well-accepted standard for performance evaluation.

Another difficulty with using simulation for high-stakes testing at a neutral site is that the operating room equipment would rarely be the same as that used by the candidate, and the operating room staff's operational protocols could differ from the protocols familiar to the candidate. In the training situation, these difficulties can be overlooked as part of the global suspension of disbelief needed to maximize the benefits of simulation training. In the test situation, these differences potentially could skew the results. This issue could be addressed by allowing candidates preparing to take their examination to undergo sufficient practice sessions to familiarize themselves fully with the standard simulation environment used for the test.

Another application of simulation-based performance assessment would be for the evaluation of trainees or experienced clinicians who have been placed on probation or for whom dismissal from their position is already a distinct possibility. For these clinicians, the burden of proof is on them to show their skills. Simulation could offer a more controlled environment for these clinicians to do so. The same could be true for practitioners who wish to return to clinical work after a hiatus.

The existing systems of performance evaluation, which use a haphazard composite of subjective judgment of clinical competency in clinical work along with written and oral examinations, has itself never been validated. Many experts believe that the written examination does not correlate well with clinical ability, and the degree to which the oral examination process tests actual clinical skill is unknown. Simulation could offer candidates the opportunity to show their clinical abilities in a controlled clinical domain; appropriate scenarios can probe language skills and the ability to act as an effective consultant to other clinicians.[226,366]

The ABA transitioned in 2017 to a new format for the Part 2 Examination, named the APPLIED Examination, to include an Objective Standardized Clinical Examination (OSCE) component along with the traditional structured oral examination component. The OSCE stations do not include full-scale mannequin-based simulation but do include performance on task trainers and encounters with actors playing roles as patients or as clinical personnel (e.g., surgeon).

The methods currently used to assess the performance of clinicians in their actual clinical work are weak and inconsistent; systematically incompetent anesthesia professionals are not easily identified or removed from practice. Thus, reasonable arguments can be made that the field of performance assessment has advanced sufficiently to allow consideration of simulation-based examinations, including full mannequin-based simulations, even for high-stakes purposes, especially considering the limitations of the current systems of written and oral examination.[366] Nonetheless, simulation-based performance assessment remains a controversial topic for discussion in the simulation and clinical anesthesiology communities. The anesthesia professions should be careful about how they may introduce simulation-based performance evaluation. The controversy should not divert attention from the most common application of simulation, which is to improve clinical performance through training individuals and teams to prevent and manage adverse clinical events.

Simulation Societies and Simulation Journals

One measure of the evolving maturity of simulation in health care is the formation and growth of professional societies and associated peer-reviewed journals. Organizations such as the Society for Simulation in Health Care (SSH) and the SESAM (www.sesam-web.org) have been constantly striving to promote knowledge and use of simulation in health care. Although anesthesiology was the medical field that initiated work on the fully interactive mannequin-based simulator and that dominated the early developments in the field, simulation is a broad strategy that has now been widely adopted by many different disciplines and domains in health. For the most part, simulation professional societies have sprung up as explicitly multidisciplinary organizations, while clinical societies have also created committees and other bodies to oversee or facilitate the use of simulation in their settings. Major leadership roles in the multidisciplinary societies have been played by anesthesiologists and engineers associated with anesthesiology far more frequently than their prevalence in the clinician population would otherwise predict.

Periodic scientific congresses on simulation such as the Rochester Conferences on Simulation in Anesthesia have been under way since the mid-1990s although attendance was less than 100 people. The largest simulation organization is SSH, which was founded in 2004 as the outgrowth of the group that had operated the International Meeting on Medical Simulation for several years as a satellite to the annual meeting of the Society for Technology in Anesthesia. Under the auspices of SSH, the meeting was transformed into the IMSH, encompassing all health care disciplines and domains, not just medicine. Although starting with far fewer attendees, the annual meeting of SESAM now has around 850 attendees (2018). Similarly, for SSH, whereas the original IMMS had at most 200 attendees, IMSH in 2018 had more than 3000 attendees. For IMSH this number places it in the category of a medium-sized scientific meeting; to put this in the context of anesthesiology, it would rank as the third largest meeting in the United States, falling below only the ASA meeting (about 14,000 attendees) and the New York Postgraduate Assembly in Anesthesiology (PGA) conference (over 4000 attendees), but ranking ahead of the International Anesthesia Research Society (IARS) annual meeting (about 1000 attendees).

Another sign of the growing maturity of simulation in health care is the establishment and growth of peer-reviewed journals for the field. SSH has published *Simulation in Healthcare* in print and online every other month since 2006. This journal was approved for indexing by PubMed in 2008. Many organizations have become affiliates of SSH and most have made *Simulation in Healthcare* their official publication (for example the Australian SSH, and the Association of Standardized Patient Educators). The International Nursing Association for Clinical Simulation and Learning has published (online only) the *Journal of Clinical Simulation in Nursing* since 2006 although it rarely has papers concerning anesthesiology. The BMJ *Simulation and Technology-Enhanced Learning*, the journal of the UK Association for Simulated Practice in Healthcare, has been published (online only) since 2014. *Advances in Simulation*, the official journal of SESAM, has been published (online only) since 2016.

The Future of Patient Simulation in Anesthesia

The future is now—we are it.[234]

More than three decades of consistent development have passed; the field of simulation in health care could be described metaphorically as being in its adolescence or young adulthood. Thousands of simulators are in use around the world in thousands of clinical programs. Anesthesiology and critical care remain important mainstays in simulation, which is now a standard part of the training of anesthesia professionals, although these fields have now become minority users when compared to numerous users across all the rest of health care. Yet even in anesthesiology, with nearly 30 years of simulation under its belt, the fraction of anesthesia professionals who have undergone a serious simulation experience since completing their initial training is relatively small. For example, as of 2018 Gaba estimates that only about 25% of board-certified anesthesiologists in the United States have undergone the MOCA simulation course.

The modalities of simulation have expanded from completely nontechnological to fully virtual. MBS have become more sophisticated, easier to use, and more portable, and available in many different models from multiple manufacturers. On the other hand, considering that it is now nearly 25 years since the first commercial simulators were introduced, the overall improvement in the features, reliability, and clinical or physical realism has not advanced at nearly the rate as for computing equipment over the same period. In part this is due to the fact that improvements in simulators depend heavily on the demand for the devices in general, and for special features in particular. There is a steep tradeoff between features and many otherwise desirable improvements may be too costly for their expected impact or demand. Simulators that use complex mathematical models of physiology and pharmacology have largely retreated from the marketplace since many applications can be managed well with less complicated control systems.

In contrast to aeronautical engineers designing airplanes, anesthesia professionals or biomedical engineers do not design and build human beings. In aviation the fundamental differential equations of fluid mechanics and aerodynamics are firmly established, allowing supercomputers to provide technically meaningful simulations as replacements for many physical tests; furthermore, test flights of prototype aircraft are conducted with sophisticated instrumentation built in to test and carefully capture their behavior. Clinicians will never have this type of knowledge about the human body.

VR and AR are still in an early childhood phase, with rapid development under way but with maturity still far away. Many current (late 2018) VR systems address visualization of anatomy or physical structures. Only a few provide multiparticipant interaction in an immersive virtual environment. As far as the virtual patient is concerned they are only as good as the underlying engines—mathematical or otherwise—that drive their clinical responses. The coming decade(s) will likely see a continued proliferation of VR systems with substantial shakeout of techniques, technologies, and firms. Currently many users of simulation are beginning to try out VR and AR systems but it is still very early in their development and use.

VR proponents imagine a VR so realistic that it rivals, or is indistinguishable from, the real world. This would approach the *Star Trek* holodeck or the “brain in a vat” style of simulation in *The Matrix*. Although we once predicted that interactive VR could take over from physical simulation by 2020 to 2025, and the tide has indeed started to turn, we predict that it will still be a long time—if ever—before this happens. Whether there is indeed something fundamentally different about human professionals working together naturally in a physically realistic clinical environment versus doing the same via some sort of VR remains to be seen.

Patient simulation has now become a regular part of initial and recurrent training of most anesthesia professionals and many other clinicians in many countries in the developed world, and significant penetration into the developing world. Zero to low technology simulations are also being used successfully in low resource areas to address important health issues.

With patient simulation issues of human factors and patient safety, in part via the CRM concept, were introduced to health care as ACRM training and its equivalents in various clinical arenas. This has been an influential complement to traditional methods and content of teaching and learning in a large variety of health care domains, especially those that share the complex and dynamic work profile of anesthesiology—decision making playing out over seconds, minutes, and hours; working with action teams; wielding highly lethal interventions as described in Chapter 6. Since all of the pioneering work on mannequin-based simulation and its key applications was done in anesthesiology, our field can rightly claim to have given one more gift to all of health care, to accompany other gifts such as the Apgar score, modern pulse oximetry and capnography, blood gas analysis, mechanical ventilation, etc. Moreover, despite its wide spread beyond anesthesiology, anesthesia professionals and others working with them continue to play major leadership roles in multidisciplinary and multiprofessional simulation centers and organizations.

Fully integrated simulation team training with a significant focus on human factors and CRM may improve patient safety and quality in acute care settings, and it may increase employee satisfaction and effectiveness of routine work. Simulation team training is becoming more common, but is still not solidly embedded into the fabric of health care as a core part of how we do business as is the case for commercial aviation or nuclear power. While health care has a long way to go to achieve the full impact of simulation on the quality and safety of patient care, the authors no longer fear that the technique of simulation will be rejected in our field, and they believe it is worth it to remain on a path toward the comprehensive industrywide, career-long application of simulation to save as many hearts, brains, and lives as possible.

Ethical Aspects of Anesthesia Care

GAIL A. VAN NORMAN and STANLEY H. ROSENBAUM

KEY POINTS

- Deontologic ("rules-based") ethical theory and utilitarian (outcome-based) theory clash in clinical scenarios in which the interests of individual patients are pitted against the interests of larger populations.
- In the United States, the predominant medical ethical principle is that of respect for the patient's autonomy, and its expression is in the informed consent of patients for medical therapy.
- Competent and autonomous individuals can make affirmative choices about their medical care and refuse any medical treatments, including lifesaving care. Competence is both functional and relative. Four elements of competent decision making are understanding, appreciation, reasoning, and evidence of a choice.
- Minor patients have varying degrees of decision-making capacity, and they may have legal rights to make certain decisions. Pediatric patients should be involved to the degree that they can be in medical decision making, particularly regarding elective therapy.
- Medical testing should follow the ethical principles of beneficence and nonmaleficence and should be based on clinically validated algorithms whenever possible. Medical tests with special social significance, such as pregnancy and human immunodeficiency virus testing, should be undertaken only with the patient's informed consent and should not be undertaken without sound evidence that they are necessary and beneficial.
- In general, the rights of pregnant women are weighed against the rights of fetuses in a decremental fashion as the fetus approaches and surpasses viable age. Laboring women are able to give informed consent, and the validity of "Ulysses directives" at the time of labor is ethically arguable.
- Use of restraints is antithetical to promotion of autonomy, and anesthesiologists have both ethical and legal obligations to determine whether such extreme intervention is warranted. Coercing or using physical or chemical means to force competent patients to undergo treatment they are refusing is both unethical and illegal.
- Respect for patients' autonomy requires that we disclose mistakes to release patients from misconceptions about their medical past and enhance their ability to share decision making about their medical care.
- An advance directive is a document executed by the patient before incapacity to provide the patient's physicians with guidance in medical decision making when the patient cannot communicate for himself or herself: these directives include, but are not limited to, durable powers of attorney, living wills, transfusion decisions, do-not-attempt-resuscitation (DNAR) directives, and decisions regarding organ donation.
- Surrogate decision makers explicitly act in "substituted judgment" to provide what the patient would have wanted and are not being asked merely for their own preferences. Surrogate decision makers at best only approximate the patient's decisions.
- Patients have moral and legal rights to refuse even life-sustaining therapy, including in the operating room. DNAR orders should not be automatically suspended for anesthesia and/or surgery, but rather require reconsideration of risks and benefits; the goals and decisions of competent patients should generally be honored.
- Terminal care requires special knowledge and experience on the part of the physician. It requires expertise in medically supportive therapy, management of problematic symptoms, knowledge about physiologic changes in the dying patient, support and counseling of patients and families, understanding and respect for the patient's autonomy and religious and cultural practices and beliefs, the ability to work within complex healthcare teams, the ability to communicate well, and empathy.
- Several interventions have special ethical implications—fluid and nutritional management; the administration of sedatives and/or narcotics that have the potential to hasten death; the institution of deep continuous sedation; the administration of neuromuscular blocking agents; and deactivating pacemakers, ventricular assist devices, and implanted cardioverter-defibrillators.

- Physician-assisted suicide (PAS) is the provision of medication and/or prescriptions to patients at their request for the purpose of ending their life. Euthanasia is the administration of medication by someone other than the patient for the express purpose of causing death. PAS and euthanasia are legal only in specific parts of the world, but they are strongly supported by the public.
- Brain death is legally and medically defined as the point at which all cardiorespiratory function irreversibly ceases *or* all function of the whole brain irreversibly stops.
- In donation after cardiac death (DCD), withdrawal of life support occurs with provisions for immediate organ donation after cardiac arrest. Controversies around DCD include concerns about when cardiopulmonary death can be declared and whether medications that preserve organ function but may hasten the donor's death can be administered.
- Research in human subjects must balance many conflicting interests such as the needs and rights of the research subject; the hypothetic interests of future patients; and the physician's financial, professional, and personal goals. The ethical conduct of research in human subjects follows three principles: (1) respect for autonomy, and the obligation to protect subjects with limited autonomy; (2) beneficence, with obligations to minimize risks, maximize benefits, and ensure that the research design is scientifically sound; and (3) justice, the obligation to treat each person with regard to what is morally right and to ensure fair distribution of benefits and burdens.
- Advances in understanding animal cognition have led most biologists to believe that many, if not all, animals are capable of feeling pleasure, pain, anticipation, and fear, and thus they experience both enjoyment and suffering. Allowing animal suffering because of pain, fear, sickness, or poor standards of care is a moral harm that must be avoided, mitigated, and weighed heavily against the benefits it produces.
- U.S. professional organizations for physicians have consistently stated that participation in executions by physicians is unethical, and the American Board of Anesthesiologists states that participation in executions would constitute unprofessional behavior that would result in investigation and possible decertification of anesthesiologists.
- "Conscientious objection" by physician to providing legally allowable medical care that violates their personal moral values is possible, but is limited and counterbalanced by a physician's professional obligations to put the patient's interests first.

Medicine is a respected profession with codes of behavior and definite rules of conduct. Modern medical practitioners have tremendous power, recognized social import, and powerful financial interactions that touch nearly everyone's lives. The American Society of Anesthesiologists (ASA) has established principles for the ethical management of patients.[1] This chapter examines the ethical bases of the practices of medicine and the implications for anesthesiologists.

Ethical Theory

VIRTUE ETHICS, UTILITARIANISM, AND DUTY-DRIVEN ETHICS

The classic "paternalism" of medical practice was derived from *virtue-based ethics.* In this view, the physician is a genuinely virtuous person with inherent qualities of competence, sincerity, confidentiality, and altruism, who naturally knows and does what is correct for the patient. The patient, uneducated about medicine, has to trust the physician to decide what is best. Western society and legal systems have changed substantially since paternalism flourished, giving way to practices based in the four "pillars" of medical ethics: respect for patient autonomy, beneficence, nonmaleficence, and justice. Many different ethical frameworks are applied in modern medicine, but two of the most prominent frameworks relevant to western medicine are utilitarian ethics and deontology.[2]

In *utilitarian ethics*, actions are judged right or wrong on the balance of their good and bad consequences. A "right" action produces the most good, based on a perspective that gives equal weight to the interests of all affected parties. Utilitarian theory is compelling but falls short in defining which benefits are most important. Is it the "good" that all reasonable people want or the "good" defined by the individual patient? What if the only way to maximize good is to commit an entirely immoral act? For example, what if the only way to win a war is to systematically torture children? Outcomes of actions continue to accumulate over time—when on that continuum is it appropriate to determine that an action was right or wrong? The "good" act of saving an individual's life today may be viewed through a completely different lens when, 20 years from now, that same individual is revealed as a mass murderer.

Utilitarian theory may be best when applied to analyzing broad-based policies, in decisions regarding rationing of resources, and when attempting to resolve conflicting ethical obligations between several equally interested parties.

The premise of Kantian-based ethics (also called deontologic—or *duty-based*—theory) is that features of actions other than their consequences make them right or wrong. *Intention* is more important than outcome. Furthermore, no person should use another exclusively as a means to an end, because each person *is* the end for which we should act. No person should be used to further the purposes of another person without that other person's autonomous consent. Kantian philosophy would forbid killing one innocent person to save another innocent person, for example.

Individualism and autonomy are valued highly in Western society, and people tend to turn to Kantian philosophy when ethical questions arise that balance the authority of the physician against the goals and values of individual patients.

Some of the toughest ethical questions in medical practice occur when the rights and desires of individual patients conflict with social policies. Clashes between deontologic and utilitarian principles are common in the intensive care unit (ICU), in managed care settings, in end-of-life care, in transplant medicine, in triage during civilian mass casualty events, and in the care of poor and older patients whose medical management is funded by the government. In each of these settings, the will of the individual patient may conflict with broader principles of minimizing expense, fairly allocating scarce resources, protecting the broader interests of many patients, and determining where and how society's healthcare dollars are best spent.

The political tradition of the United States provides a clear underpinning to individual freedom, and at the beginning of the 20th century, the concept of the autonomy of patients began to emerge.

Clinical Ethics

INFORMED CONSENT AND INFORMED REFUSAL

Legal and moral imperatives for informed consent are based on the ethical principle of respect for patient autonomy. *Autonomy* refers to the ability to choose without controlling interferences by others and without personal limitations that prevent meaningful choices, such as inadequate information or understanding.[2] Individuals have the right to determine what happens to them to the degree to which they are capable. In the United States, this right is rooted in constitutional guarantees of privacy and noninterference.[3] In 1914, the case of *Schloendorff v Society of New York Hospital* established that it was the right of "every human being of adult years and sound mind to determine what shall happen to his own body."[4] In 1957, the term *informed consent* was first used in the case of *Salgo v Trustees of Leland Stanford Hospital*, which established that it is not sufficient for physicians simply to secure consent; physicians have a duty to inform patients about the risks and alternatives to treatment, in addition to the procedures themselves and their consequences.[5]

Respect for the patient's autonomy requires physicians to respect decisions made by competent patients, but also to *promote* autonomy by removing barriers to competent participation in decisions. Such obstacles range from incomplete or inaccurate information to reversible medical conditions that impair a patient's ability to understand the information given to him or her.

Competence and Capacity

Autonomy to make medical decisions cannot exist in the absence of competence. In the United States, *competence* is a legal determination, and *capacity* describes the necessary skills to participate in medical decisions. Most often, the terms are used interchangeably.[3]

Impairments of capacity can be temporary or permanent. Examples include some mental illnesses, dementia, immaturity, anxiety, and pain. Medication effects can variously impede competence, or improve it, depending on their effects and the context in which they are given. Older patients, patients suffering from mental impairment, and children are particularly vulnerable to having their participation in medical decisions inappropriately curtailed or denied because their capacity to participate is frequently underestimated. Hearing loss, expressive aphasia, and other neurologic impairments can create the false impression that capacity is impaired. Many minors have the ability to make medical decisions but may be mistakenly excluded from the decision-making process solely because of their age. Language barriers can present significant challenges to communication.

Capacity is both relative and task specific. Patients may be able to understand and make decisions about medical issues while being unable to manage their financial affairs, for example.

Prejudice and paternalism permeate physician behavior in the informed consent process. Challenges to a patient's competence frequently occur because the patient and the physician have a difference of opinion or values,[3,6,7] and the majority of referred patients are found competent.[3] Unwarranted challenges of a patient's capacity may, intentionally or not, serve to allow the physician to dismiss, rather than solve, a dilemma regarding a difficult patient's wishes, since with a finding of incapacity, the physician's paternalism cannot then be trumped by patient autonomy. In a retrospective study, Katz and associates commented that referrals for urgent or serious treatment put pressure on a consulting psychiatrist to support the medical team's wishes for intervention by simply declaring the patient incompetent.[8] Treatment refusal may simply reflect a patient's prioritization of other things (e.g., dignity, privacy, independence) other than medical outcomes, and not a problem with capacity—or it might reflect manageable emotions and values that disproportionately affect a patient's choices, but do not necessarily rule out capacity.

Doctors are mistaken about patients' preferences regarding life-extending therapies and underestimate older patients' desires for life-extending therapies in 30% to 40% of cases.[9,10] Moreover, surveys indicate that physicians and other healthcare workers are likely to *act* on their personal prejudices regarding handicapped or impaired patients.[11]

Functional capacity for decision making must be judged separately from the perceived quality of the decision itself. Patients have the right to make "bad" decisions (i.e., decisions that *the physician* feels are less than optimal) if they are competent and have appropriate information.[7] Otherwise, the physician would merely prevail whenever a disagreement occurred, and patient autonomy in medical decision making would be nonexistent.

How do we recognize competence? Competence is defined *functionally*, and it *is task specific*.[2] It cannot be defined to be absent by the mere presence of specific diagnoses or medications.[12] Furthermore, evidence of *impairment* is not sufficient to prove *incompetency*. With such high value placed in the United States on autonomy and self-determination, incompetency is, and should be, a difficult bar to leap over, requiring that only persons with impairments "that place them at the very bottom of the performance curve" should be declared incompetent.[12] A "sliding scale" approach to competence determinations, rather than an all-or-none approach, is endorsed by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research,[13] and generally reflects how courts deal with competency cases.[12]

Anesthesiologists frequently ask whether valid consent can be obtained after the patient has received premedication. Claims that premedications automatically invalidate consent demonstrate a lack of understanding of the concept of competence. If it were true that benzodiazepines and narcotics, for example, automatically invalidate consent, then we would have to consider the consent of almost all chronic pain patients invalid. In one study, 37.5% of geriatric patients presented for surgery having taken self-prescribed medications and over 25% of these were analgesics and benzodiazepines.[14] If competence were automatically invalidated by the presence of specific medications, then we would be forced to carry out drug testing on all preoperative patients before obtaining consent. While it is true that *sometimes* premedication can interfere with a patient's ability to give consent, in some circumstances, patients cannot give consent *without* premedication. A patient who is in severe pain, for example, is unlikely to be able to focus on detailed risks and alternatives of a proposed procedure without first receiving medication. In that case, treatment of severe pain may actually *improve* competence during the informed consent process.

How does the anesthesiologist determine if they are dealing with a competent patient? Multiple reviews by competency consultants agree that there are several functional elements to competence: (1) *Understanding* - Can the patient receive and understand treatment-related information? (2) *Appreciation* - Does the patient have insight about the disorder and its consequences and potential treatment options? Does the patient understand that treatment could be beneficial in some way? (3) *Reasoning* - Is the patient able to use logic to compare the risks and benefits of treatment alternatives? And, (4) *Evidence of a choice* - Can the patient communicate a choice?[3,12,15]

In respecting and promoting patient autonomy in medical decision making, the anesthesiologist has an ethical duty to treat reversible conditions that interfere with medical decision making when doing so would not delay the medical treatment so much that it becomes irrelevant. Elective surgery may have to be postponed until expert consultation for a determination of mental capacity or treatment of reversible conditions can occur. When surgery in an impaired patient is urgent, the anesthesiologist may have to rely on a surrogate decision maker or proceed with the best determination of the patient's interests in mind. It is important to note that the mere presence of an emergency does not invalidate a *competent* patient's rights to consent to or to refuse treatment. Overriding a competent patient's wishes is unethical, even in emergency situations.[16]

Disclosure

The informed consent process requires honest disclosure of medical information to the patient. U.S. courts generally rely on two standards of disclosure, termed the reasonable person (or objective person) standard and the subjective standard. In the reasonable person standard, the physician must disclose any information that a theoretically reasonable person would want to know, and the risks or cluster of risks to which a reasonable person in the patient's position would attach significance in deciding whether or not to forgo the proposed therapy.[17,18] This standard does not require an exhaustive recitation of facts, and it acknowledges that not all information related to the procedure is integral to making a decision about whether to undergo that procedure. The subjective standard recognizes that some patients may have special needs for specific information, and when that need is obvious or has been brought to the attention of the physician, the information must be disclosed. A concert violinist may have a specific need to know about the potential for nerve damage from an axillary block, while an opera singer may need to know that intubation may adversely affect the voice. In obtaining informed consent, the anesthesiologist should always ask the patient if there are any special concerns regarding the anesthetic, or anything he or she would want the provider to know. In general, legal and ethical standards now require that the physician (1) accurately discuss the therapy and its potential alternative—including no therapy—and (2) disclose the common risks, because they are more likely to happen, and the serious risks, because the consequences are severe.

The doctrine of *therapeutic privilege* is sometimes cited to avoid discussing risks, the reasoning being that discussing risks can psychologically or physically harm the patient by increasing stress. Studies of patients' stress during the informed consent process *do not* support this concept. These studies show that patient stress is generally reduced after risk discussions[19,20] and omission of such conversations is contrary to U.S. law. Although it is ethical to forgo or curtail risk discussions at the patient's request, it is not ethical for the physician to decide to do so unilaterally.

The physician-patient relationship is inherently unequal because of the physician's knowledge and authority and the patient's dependence on the physician for care. Physicians have ethical obligations to avoid exploiting their influence for the purpose of accomplishing their own ends. Although offering a rational basis for a medical choice is acceptable, it is always unethical to coerce or manipulate competent patients into decisions by presenting real or implied threats or by omitting or misrepresenting key information. In fact, such intentional manipulations are morally equivalent to lying to the patient, and thus invalidate the concept of informed consent entirely.[21]

Legal Implications of Informed Consent

The informed consent process does not prevent legal liability when adverse events occur. Flawed informed consent processes have been cited, however, as evidence of a lack of quality of care by the physician, and are associated with poorer litigation outcomes for the physician.[22] The ASA closed-claims database reveals that informed consent is cited in approximately 1% of cases, and cases with inadequate informed consent documentation are associated with larger monetary awards.[23] Studies show that the risk of a malpractice claim is directly related to the patient's perception of his or her relationship with the physician.[24] The informed consent process provides one of the few opportunities anesthesiologists have to establish that relationship, however brief, and the medicolegal importance of that process should not be underestimated.

Informed Refusal

The concept of informed consent is moot if the informed patient cannot refuse medical therapy, because every informed consent process would then have to end with the physician getting his or her way. Examples of informed refusals in anesthesiology include requests to withdraw or withhold life-supporting care in the ICU; do-not-attempt-resuscitation (DNAR) orders in the operating room; refusals of blood transfusions; and cases in which a patient refuses preoperative testing, such as human immunodeficiency virus (HIV) or pregnancy testing.

Informed refusal has concerns and requirements similar to those of informed consent. When patients refuse medical care or insist on what the physician believes to be suboptimal care, disclosure of the risks and benefits becomes even more important because these decisions may veer from options that are already widely accepted and for which the risks are believed to be lowest. It is easier to justify agreeing to the unusual preferences of a well-informed patient than to justify subjecting a poorly informed patient to unorthodox care.

Despite full information, patients may sometimes request or demand care that is unreasonable, either because it will adversely affect the performance of a surgical procedure or because it would be associated with unreasonably high risks. When a patient demands a technique that is inappropriate or outside of the realm of reasonable practice, the anesthesiologist is under no ethical obligation to provide that care. No physician can be compelled by a patient to practice negligently.

Special Issues in Informed Consent and Informed Refusal

THE JEHOVAH'S WITNESS PATIENT

The classic example of a patient who refuses therapy in anesthesia practice is that of Jehovah's Witnesses, many of whom believe that accepting a blood transfusion violates a Biblical injunction. The Jehovah's Witness doctrine has been subject to change over time, with resulting inconsistencies in religious practice regarding which, if any, blood components may be acceptable. Individuals interpret religious doctrines in light of their own spiritual contexts, and not all believers hold to the same tenets with identical fervor. Church doctrines, like medical practices, evolve over time, and practices that are acceptable at one time may not be years later. Anesthesiologists and surgeons have cited individual and doctrinal inconsistencies as justification for ignoring the wishes of Jehovah's Witness patients, but to do so is no more logical than assuming that every hypertensive patient needs or will respond well to identical treatment or that optimal treatments will not evolve over time. Moreover, *any* patient has the right to refuse blood transfusion therapy, regardless of whether this desire is founded in religious preference. Such refusals have become more common in patients who are not Jehovah's Witnesses, as blood transfusion therapy has been connected to infection risk and other complications.

Because of the differing beliefs of Jehovah's Witness patients, the anesthesiologist must have a thorough and detailed preoperative discussion of possible therapies with the patient, and the conclusions should be documented in the patient's chart. A physician who cannot comply with a competent adult patient's desire to forgo transfusion has an ethical obligation to find an alternative caregiver whenever possible.[25,26]

The courts strongly support the rights of most adult patients to refuse blood products for themselves but have been inconsistent and have interfered in cases of some pregnant patients. Transfusion of pediatric Jehovah's Witness patients by court order is common. However, this may become ethically and legally less acceptable as alternative bloodless therapies to maintain oxygen-carrying capacity evolve, as the Jehovah's Witness church further defines its doctrines with regard to children, and as the capacity of children to consent to or refuse therapy is better understood.

THE PEDIATRIC PATIENT AND OTHER PATIENTS WITH IMPAIRED COMPETENCE

The ethical practice of medicine weighs heavily toward adherence to the respect for autonomy of competent patients or advance directives of patients who were previously competent. Medical care of individuals who have never been autonomous relies on principles such as respect for human dignity, beneficence, avoidance of harm, and adherence to the principle of justice.

Children are examples of persons who may or may not yet be autonomous. Laws in each state define the age at which children become legally competent to make medical decisions (usually 18 years), but many younger children have the mental and emotional capacity to make medical decisions. Forcing such individuals to undergo treatments they do not want is unethical and could be illegal as well.

Decision-making capacity in children is variable. Most 2-year-old children are clearly not able to make medical decisions. However, the range of capability in children as young as 7 or 8 years old is wide. In one study, children 6 through 9 years of age who were invited to participate in influenza vaccine research asked pertinent questions about individual risks and benefits and whether their community and other children would benefit.[27] Studies suggest that the average 12-year-old adolescent has capabilities that are required in medical decision-making, but differing influences of the brain's well-developed reward system coupled with underdevelopment of the brain's control systems suggest that decision-making capacity may in fact be diminished in specific contexts in this age group.[28]

Most states recognize "emancipated minor" status, in which a court determines that a minor can legally make medical decisions for himself or herself. Legal exceptions to the age of consent are recognized in most states when treatment is believed to be in the minor's best interest and when a requirement for parental consent would interfere with the child's ability to receive medical help. The law recognizes that, tragically, some conditions for which a minor seeks therapy may even be the result of parental abuse and seeking parental permission for treatment may actually further endanger the minor. One quarter of pregnant teens are at risk for physical or sexual assault, and the most common perpetrator is a member of their family.[29] Thus, minors are allowed in many states to consent for treatment for substance abuse, sexually transmitted disease, mental illness, and medical care affecting pregnancy, including abortion, without seeking parental consent. When a minor has decision-making capacity but is not "emancipated," a judge may declare the child to be a "mature minor" with decision-making rights.

Ideally, individuals of any age should be involved in medical decisions to the degree that their capacity allows. Children ages 7 to 17 have been shown to desire comprehensive perioperative information, including details of the procedure and anesthesia, risks, and complications.[30] A minor with capacity to make decisions should not be coerced or restrained under most circumstances.[31] Determining whether a minor has such capacity may require formal consultation and assessment. The American Academy of Pediatrics has stated that physicians who care for children "should give serious consideration to each patient's developing capacities for participating in decision making, including rationality and autonomy."[32] The term *assent* rather than *consent* is used to refer to agreement to treatment from children who do not fall into legal categories, such as age, that award adult rights. Recently, authors have suggested that informed *consent* rather than *assent* for medical research participation should be applied to children ages 12 and up.[33]

When children dissent from medical care, persistent refusals may be ethically binding, particularly in the case of participation in research. Medical personnel should respect the wishes of a patient who withholds assent and should try to gain a better understanding of the patient's situation or deal with his or her fears. "A patient's reluctance or refusal to assent should also carry considerable weight when the proposed intervention is not essential to his or her welfare and/or can be deferred without substantial risk."[32]

Ethical Challenges of Preoperative Testing

The ethical implications of genetic testing have been widely discussed in the literature, but the ethical implications of routine medical testing have been largely overlooked by professional societies. The performance of diagnostic tests does have ethical dimensions, however. We generally undertake such tests precisely because we intend to help the patient (beneficence) or to use the information to minimize other risks (nonmaleficence). Certain medical tests may also carry implications for the patient's autonomy, privacy, and even social justice.

ROUTINE PREOPERATIVE TESTING PROTOCOLS

Preoperative testing may help identify unrecognized or disguised conditions that could adversely affect anesthetic risk. All medical tests carry risks, however. False-positive and false-negative results may either label patients as having a condition they do not have or inappropriately assure patients that they do not have a condition that they do. Erroneous results may lead either to further testing or to inappropriate and unnecessary therapy associated with further complications. Errors can also cause patients to be deprived of important therapy they would otherwise receive. Tests sometimes have accompanying physical complications, and they are certainly always associated with economic costs. Systematic over-testing increases the costs of health care for entire populations, unnecessarily burdening an already costly system, and diverting badly needed funds to unnecessary enterprise. Medical tests may involve problems of conflicts of interest if the ordering physician has an economic relationship with the entity that carries out the tests. Additionally, not all medical tests are ethically equivalent. Certain tests, such as pregnancy testing and HIV testing, may have complex social consequences and can lead to serious, avoidable harms.

Modern medicine is a science that incorporates theories that are expected to be consistent and generalizable. Although all data are deeply theory laden, the practice of evidence-based medicine (EBM) is founded on the concept that conscientious, judicious, and explicit use of the best available medical evidence should be integrated with clinical experience derived from systematic research in making decisions about the medical care of individual patients. In general, nonsystematic clinical experience, anecdote, and untested theory are not sufficient grounds for clinical decision making.

EBM and medical ethics share common principles and goals: both are aimed at maximizing benefits and minimizing risks, as well as at involving the patient in shared decision making. Using EBM to guide clinical testing and therapy is supported by analysis of traditional therapies that were never subjected to rigorous testing and that, on examination, were shown to be not only unhelpful to patients but possibly harmful. One Cochrane review, for example, found that administration of human albumin, a mainstay of therapy for treatment of shock, may be associated with increased mortality.[34] Another Cochrane review demonstrated that although mammography screening will prolong the life of 1 in 2000 women over a 10-year period, it will lead to the false diagnosis of cancer and the institution of cancer treatment in 10 women during that same period; these findings raise serious questions about the benefits and risks of routine mammography.[35] Using systematic evaluation of medical diagnostic testing to develop principles of preoperative testing not only serves the ethical principles of beneficence and nonmaleficence, but also permits us to provide patients with accurate and up-to-date information on the potential benefits of tests to aid their understanding and input in their medical care—thus honoring the principle of respect for the patient's autonomy.

Conversely, EBM presents potentially significant ethical concerns. In relying on traditional medical experimentation, EBM may not sufficiently account for the role of social and cultural factors (e.g., poverty, ethnicity, spirituality, and gender) in health, and instead may rely too heavily on a narrowly drawn biomedical model of the patient's experience of health and disease. In the words of Rogers, "those with the greatest burden of ill health are disenfranchised, as there is little research that is relevant to them, there is poor access to treatments, and attention is diverted from activities that might have a much greater impact on their health."[36]

Despite its limitations, it nevertheless seems reasonable to believe that in trying to maximize beneficence and minimize nonmaleficence, EBM provides at least an improvement in the search for a rational, cost-effective approach to medical testing over simply adopting "traditional" therapies or protocols without evidence that they will contribute to accomplishing those goals. Applying medical tests inappropriately can cause very real harm to patients. Simply stated, if medical care is not valid, then it is not ethical.

Evidence that routine tests or traditional patterns of preoperative testing enhance perioperative outcomes is scant. Large population studies of many routine preoperative tests, such as coagulation screening,[37] chest radiography,[38] and electrocardiography,[39] have, on the contrary, found that these tests increase costs without necessarily positively affecting outcomes and can even lead to detrimental outcomes. The ASA Task Force for Preanesthesia Evaluation acknowledged that most routine testing is not necessary.[40] When evidence-based algorithms for preoperative testing are available and have been appropriately validated clinically, they should be used to guide clinical decision making.

ROUTINE PREOPERATIVE PREGNANCY AND HUMAN IMMUNODEFICIENCY VIRUS TESTING

Social risks of preoperative testing may not be as obvious to the physician as medical risks, but they can be the source of significant harm. Examples of tests that can produce social harm and are of limited preoperative utility are HIV and pregnancy tests. Both tests have serious ethical consideration; have limited, if any, beneficial impact in the setting of surgery; may have serious social and economic consequences for the patient beyond the operating room; and require the patient's informed consent.

HIV tests are often ordered for the purpose of singling out patients for whom extra universal precautions could be taken to reduce transmission in the operating room. Most surgeons and anesthesiologists believe that compulsory HIV testing would reduce their risk of exposure, and many believe incorrectly that this testing is the physician's prerogative and can be done without the patient's consent.[41]

However, HIV testing does not necessarily yield safer anesthetic management and is more costly than diligent application of universal precautions.[42] In low-prevalence populations, testing is more likely to give false-negative results that wrongly reassure operating room workers that a patient is not infected. This may paradoxically increase the risk of HIV transmission if relaxation in vigilance is the result.

HIV tests can result in loss of employment, insurance coverage, or both. Seropositive women can experience marital breakup, abandonment, verbal abuse, and physical violence if their status is disclosed.[43,44] The threat of compulsory HIV testing almost certainly would prevent some patients from seeking needed surgical care.[41]

Routine preoperative pregnancy testing has ethical ramifications analogous to those of HIV testing. Despite pervasive beliefs to the contrary, studies do not conclusively demonstrate that anesthetic agents lead to early fetal loss, and no anesthetics have been clearly associated with teratogenic effects.[44-47] Studies have also shown that even adolescent girls generally accurately report the possibility of pregnancy when asked privately.[48] Legal ramifications of not routinely testing for pregnancy preoperatively have been virtually nonexistent, and fewer than one third of practices in the United States require such testing.[49] A positive pregnancy test may have extremely negative consequences if a vulnerable patient is in a social situation in which pregnancy is not accepted. Up to two-thirds of sexual assault victims are minors, and some are the result of child rape within the home. Abandonment, negative family interactions, and violence to the patient or her fetus, or both, may all occur, as reactions to revelation of the pregnancy, attempts to hide a sexual domestic crime, or even in some cases as "honor killings."[50] Referral of pregnant adolescents to child protective services should be considered.[49] In many states, it is illegal to disclose or even insinuate a child's pregnancy status to her parents, regardless of her age. Therefore, the anesthesiologist who discovers an adolescent patient's pregnancy has few comfortable or legal options.

Many patients may choose not to undergo an elective surgical procedure if they know they are pregnant. However, *coercing* a female patient to have a test against her wishes and that she may find insulting explicitly violates the principle of the patient's autonomy. The physician's self-interest is not adequate justification for disregarding a patient's autonomy or violating a patient's privacy. The ASA Task Force on Preoperative Testing and the ASA Committee on Ethics jointly recommended that anesthesiologists offer the *choice* of preoperative pregnancy testing to any female patient who may desire it, explain the potential risks and benefits, and obtain informed consent or informed refusal for the test.[40]

Ethics of Anesthesia Involving Pregnant Women

MATERNAL-FETAL CONFLICTS

In general, the rights of pregnant women to refuse therapy, even if it will be detrimental to their fetuses, are protected under right-to-privacy provisions in the U.S. Constitution. Those rights are weighed against potential harms to the fetus in a decremental fashion as the fetus approaches and surpasses viable age. When the fetus is of nonviable age, the mother's rights prevail. Court decisions have consistently upheld the rights of pregnant women to have abortions, to not be subjected to drug testing, and to forgo transfusions early in pregnancy. Attempts to charge women with child abuse, child endangerment, drug trafficking, murder, and attempted murder for activities deemed dangerous to their fetuses have almost uniformly failed.[51] In general, women do not lose their rights to bodily integrity and informed consent when they become pregnant, and neither fetal "rights" nor state interests supersede a pregnant woman's right as medical decision maker.

The American Academy of Pediatrics Committee on Ethics outlined conditions that in their view are necessary to override a mother's refusal of care: (1) the fetus *will* suffer irrevocable harm without the treatment, (2) the treatment is *clearly indicated* and likely to be effective, and (3) the risk to the woman is low.[52] The American College of Obstetricians and Gynecologists condemned the use of coercion in pregnant women and advocated counseling the patient carefully about risks, as well as consultation with an ethics committee.[53]

INFORMED CONSENT IN LABORING WOMEN

The validity of informed consent for epidural anesthesia in laboring women is a topic of concern to anesthesiologists, who periodically raise the question whether laboring women are able to consider and weigh the risks of labor analgesia sufficiently while they are in pain. Although ideal conditions for informed consent are often lacking during labor, it is important to realize that the ideal is seldom achieved even in elective surgical patients; therefore, it is crucial to distinguish between conditions that are not *ideal* from conditions that are not *adequate*.

Despite concerns by anesthesiologists, most studies show that laboring women have the same capacity to give informed consent as the general surgical population,[54,55] are able to recall details of the consent process long after labor is finished, and indicate that labor did not alter their decision making.[56] Furthermore, studies show that the presence or absence of labor pain has minimal effect on a woman's ability to recall analgesia risks and other elements of the informed consent process later.[55,57] Some investigators argue that it is only after the patient enters active labor and she can assess for herself the severity of pain and consequences of proceeding without analgesia that she can be fully informed.[54]

An ethical conflict can arise in the case of so-called Ulysses directives in which, before labor, a woman executes an advance directive that refuses epidural analgesia and instructs doctors to ignore her pleas for epidural anesthesia at the time of labor should she change her mind. Although some experts suggest that ignoring the Ulysses directive disrespects a woman's long-term preferences, others argue that "information and valid experience are critical prerequisites for autonomous decision making" and that only the current wish (to receive an epidural) is ethically relevant.[58] Such cases appear to have no clear and unequivocal ethical ground on which to proceed, and circumstances must guide the physician. However, if an anesthesia practice decides to disregard Ulysses directives routinely, this should obviously be disclosed to patients in advance of labor whenever possible.

The Uncooperative Patient—Coercion and Restraint

The use of physical restraint to control medical research subjects was first directly addressed in the Nuremberg Code following the Doctors' Trial in 1947 to 1949 and is a continuing subject of intense scrutiny.[59] For anesthesiologists, chemical restraints often replace physical ones, but the ethical issues are the same. Anesthesiologists are often asked by medical colleagues to chemically restrain uncooperative patients. Use of restraints is antithetical to promotion of autonomy, and anesthesiologists have both ethical and legal obligations to determine whether such extreme intervention is warranted. Coercing or using physical or chemical means to force a competent patient to undergo treatment that he or she is refusing is both unethical and illegal. Refusal of medical care and angry behavior are not proof of incompetence, intoxication, or inability to make medical decisions.[60]

When faced with the uncooperative adult patient, questions to ask include the following: (1) Is the patient clearly incompetent or merely angry and uncooperative? Does the patient show evidence of neurologic impairment, acute intoxication, or severe mental disability? (2) Is the patient in imminent danger? (3) Does the patient pose a direct threat to staff or other patients? (4) Does a compelling need to treat life-threatening injuries exist? In the absence of any of the foregoing, the use of coercion or physical or chemical restraints is neither ethical nor legal. Physicians may be forced in some situations to act within a time frame that does not permit lengthy evaluation of a patient's competence or a protracted search for a surrogate decision maker. The standard applied in such cases would be to do what a "reasonable" person would wish. Coercion or restraint (or both) in such situations is not ideal, but it may be necessary and ethically permissible.

The uncooperative child presents special ethical concerns. When a patient who does not have the capacity to make healthcare decisions dissents from medical care, the anesthesiologist is ethically required to provide care that is most likely to benefit the patient and prevent harm while preserving the dignity and safety of the patient. Although violation of respect for autonomy is technically not possible in a patient who does not have autonomy, violations of principles of beneficence, nonmaleficence, and respect for dignity certainly are. Indiscriminate use of physical or chemical restraints is not without physical risk, and the fear and anger provoked by such tactics can lead to future aversion of medical care and mistrust of healthcare providers. The American Academy of Pediatrics Committee on Child Abuse and Neglect stated that restraint should not be used in pediatric care "unless it is necessary for proper diagnosis and treatment in a sick child, as in the case of a child with a high fever and potential ear infection, or in emergency situations."[61]

Behavioral control in the uncooperative child or incompetent adult should focus on alternatives to physical restraint, such as offering choices on how to go to sleep and use of fantasy or hypnotic suggestion. Despite many possible social, economic, and scheduling pressures to the contrary, delaying or rescheduling a surgical procedure in a hysterical patient is better than using coercion or force. Delaying elective surgery may reduce stress, allow adequate premedication, and promote safer induction conditions. If medical care is urgent, or if delay is unlikely to result in better conditions for the patient, then the anesthesiologist should proceed in a manner designed to preserve the patient's dignity and safety.

Truth Telling—Disclosure of Errors and Apology

Nonmaleficence has been a foundational principle for the medical profession since the time of Hippocrates, and this principle draws no distinction between deliberate and unintended harms. Medical care is fraught with uncertainty, risk, and error. Harms resulting from unexpected complications, accidents, systems issues, and medical mistakes are to be avoided with equal diligence whenever possible.

Wu and colleagues defined a medical mistake as "a commission or omission with potentially negative consequences for the patient that would have been judged wrong by skilled and knowledgeable peers at the time it occurred, independent of whether there are any negative consequences."[62] Medical errors occur in 3% to 5% of all hospitalizations.[63] More than 40% appear to be preventable, and more than 15% result in patients' deaths.[64] In 1999, the release of the Institute of Medicine's report *To Err Is Human* focused public and political attention on the terrible fallout of medical errors in the United States.[65]

Studies showed that 76% of physicians admitted to a serious medical error that they did not disclose to the patient,[66] and 22% of physicians indicated that they would not disclose an error that caused a patient's death.[67] Reasons cited for a physician's reluctance to disclose errors included personal shame, fear of loss of prestige in the physician's cohort, fear of direct reprisal, lack of experience in disclosing uncomfortable information, fear of causing further harm (emotional or psychological) to the patient and family, and fear of litigation. In many cases, legal advice to physicians has discouraged disclosure and apology in the erroneous belief that these tactics decrease medicolegal liability.

Obfuscating the root cause of a patient's complication when it is caused by a medical error is not difficult in the physician-patient relationship because the physician has unique expertise and is the recipient of unique trust. Furthermore, a minimum standard of disclosure simply does not exist. The Code of Ethics of the American Medical Association (AMA) states that patients have a right to be free of misconceptions about their medical condition and that physicians have ethical obligations to "inform the patient of all the facts necessary to ensure understanding of what has occurred."[68] However, the AMA Code of Ethics addresses only "harms" and not "errors, thus implying no duty to disclose medical errors that do not lead to harm. Although some experts state that physicians may have a lesser obligation to disclose harmless errors and/or "near misses," it is nevertheless arguable that they should consider doing so. The physician has little to lose, and such disclosures may enhance discussion of medical care with the patient and result in a strengthened doctor-patient relationship. Legalistically, some experts consider full disclosure of medical errors to be an extension of the legal principle underlying informed consent: "Clearly, if the patient is entitled to know the risks of a procedure and what could go wrong prior to giving their consent, it follows that they would be entitled to know if something has in fact gone wrong, regardless of whether it was unanticipated."[69]

Respect for patients' autonomy requires that we disclose mistakes that harm patients because in so doing we release patients from misconceptions about their medical past and enhance their ability to share decision making about their medical care. Disclosure prevents mistaken attribution by the patient of adverse consequences to noncontributory causes. Disclosure is usually necessary for informed consent for treatments to address complications of the error. Disclosure may enhance patients' trust in physicians. Moreover, disclosure may facilitate a patient's obtaining just and fair compensation for economic consequences of the injury, such as lost work and pay.

The concern that disclosure of errors to patients will increase litigation or decrease patients' trust, either in the doctor involved or in doctors in general, has not been borne out. Studies have suggested that full disclosure of a medical error reduces the likelihood that patients will change doctors, improves patients' satisfaction, increases trust in the physician, and leads to a more positive emotional response.[70] Studies also have demonstrated that patients take legal action because they want more honesty from their physicians and assurances that the physician has learned from the mistake and that future patients therefore are less likely to suffer.[71]

An often-ignored aspect of medical errors is the effect that errors and disclosures have on physicians and other healthcare workers, who experience anxiety, fear, guilt, shame, self-doubt, anger, and disappointment. Damage to physicians, nurses, and others can be both long-lasting and severe, particularly following serious errors, manifesting as substance abuse and suicide. In a survey of anesthesiologists, 84% had been involved in at least one unanticipated death or serious injury, 88% stated they needed extended time to recover, with 19% stating they never fully recovered after the event. Twelve percent considered a career change. Even though 67% considered their ability to provide care was compromised in the first 4 hours following the event, only 7% were given time off. Five percent admitted to turning to drugs or alcohol as a coping mechanism.[72] Most anesthesiologists report inadequate support from colleagues or their institution in coping with such events.[73]

Physicians benefit from a sense of relief after disclosure and, at least in many cases, the forgiveness of the patient.[74] Disclosure helps physicians learn and improve their practice. Failures to report errors, learn from errors, and communicate errors and their potential solutions within a healthcare system are major causes of medical errors themselves. One could argue that a physician who does not disclose a preventable error, such that it is repeated, bears responsibility for harm not only to his or her own patient, but also to all future patients in whom the error could have been prevented had it been disclosed.

Disclosure can present some harm to the physician: disclosure is stressful, litigation may result, malpractice premiums may increase, and future employment may be adversely affected. However, in the doctor-patient relationship, ethical frameworks hold that benefits and harms to the patient should hold more weight than benefits and harms to the physician.

Do we have an ethical duty to disclose the errors of others? Legally, some North American courts have held that we do not,[69] and social norms about "tattling" on others are powerful deterrents to such disclosures. The reporting physician may hesitate because of a lack of definitive information, potential accusations of interfering in the doctor-patient relationship of another, worry that professional interactions such as patient referrals and performance evaluations may be affected, and fear of libel suits. When a physician observes a medical error committed by another physician, the options include nondisclosure, recommendations to the involved physician to disclose the error, disclosure of the error to a third party such as a risk-management group, or direct disclosure to the patient. Although no strict legal guidelines are in place, ethical principles favor actions that lead the patient to have a full understanding of what has occurred during his or her medical care.

Apology (as opposed to disclosure) remains a controversial aspect of communication following medical errors, largely because of fear that it could be used as an admission of negligence in subsequent litigation. Yet apology appears in many cases to decrease the risk of subsequent litigation, and lack of apology is a commonly cited reason among malpractice plaintiffs for their legal action.[75] Spurred on by a desire to reduce litigation, many states have enacted "apology laws" that prohibit use of various types of apologies in court against physician defendants in malpractice cases. The impact of these laws and the impact of apologies on the incidence and outcomes of malpractice litigation remains unclear, although significant numbers of patients who have sued physicians indicate that an apology would have prevented them from doing so.

ADVANCE DIRECTIVES AND SURROGATE DECISION MAKERS

Critical decisions regarding medical care often arise when patients are too ill to formulate or express decisions regarding medical interventions. *Advance directives* were developed after several legal decisions affirmed that patients can refuse even lifesaving medical care and that clear and convincing evidence of the patient's wishes is needed to allow surrogate decision makers to request withdrawal of life-sustaining therapies.[76] An advance directive is a document executed by the patient before incapacity to provide the patient's physicians with guidance when the patient cannot communicate for himself or herself. Such directives include the following: living wills, which detail the therapies a patient would accept or refuse in the case of terminal incapacity; DNAR orders; and any other preferences regarding medical care decisions.

A surrogate decision maker is someone whom the patient has appointed to make healthcare decisions for him or her (a durable power of attorney [durable POA]) or an individual with other legally recognized authority by virtue of his or her relationship with the patient.

A durable POA for healthcare decisions may be given by the patient to a specific person he or she designates to make healthcare decisions for them if they become incapacitated. The authority vested in a POA supersedes most other decision makers, including family members, except a court-appointed guardian.

When the patient has not designated a durable POA, doctors rely on family members to make decisions for the patient. Many states have a legally defined hierarchy of decision makers. Commonly, the surrogate hierarchy is the spouse or legally recognized domestic partner, followed by the children, if all are in agreement, then parents, if both are in agreement, and then siblings, if all are in agreement. The anesthesiologist should familiarize himself or herself with the specific laws of the state in which they practice.

Surrogate decision makers are explicitly trusted to act in "substituted judgment" to provide what the patient would have wanted and theoretically are not asked merely for their own preferences. However, surrogate decision makers at best only approximate the patient's decisions because their interpretation is subject to their own biases, values, and psychological agendas. Incompetent patients can be emotionally and financially burdensome, and decision makers may have conflicts of interest that distort their beliefs and testimony about what the patient would have wanted.

Studies demonstrate that patients and their proxies only infrequently discuss issues and values involving life-sustaining technologies. Discrepancies between patients and proxies are often significant in the assessment of patients' emotional health and satisfaction. Neither physicians nor proxies can always accurately predict the patient's preferences for life-sustaining therapies.[77,78] Nevertheless, with all the imperfections, proxy decision making may be the only option if a patient has not left specific directives.

Medical Decisions That May Require a Court Order

Some medical treatments have intense cultural connotations, may involve limitation on private freedoms such as reproduction, or may have historically been subject to abuse. Decisions regarding these interventions *cannot* be made by a surrogate decision maker (even if one is available) and require a court review. Examples of such treatments in many states include sterilization and electroshock therapy.

The anesthesiologist should review the patient's record before taking the patient to the operating room and ascertain (1) whether the patient has advance directives, (2) who the patient's surrogate decision makers are, (3) whether the procedure is legally allowed with consent from a surrogate decision maker, and (4) in special cases, whether an appropriate court order has been obtained.

Do-Not-Attempt-Resuscitation Orders in the Operating Room

Up to 60% of anesthesiologists wrongfully believe that DNAR orders are automatically suspended during anesthesia and surgery. The ASA,[25] the American College of Surgeons,[79] the Association of Operating Room Nurses,[80] and The Joint Commission[81] all published practice guidelines requiring reconsideration, not abandonment, of the DNAR orders in the perioperative period.

The causes and outcomes expected with a cardiac arrest in the operating room are different from what may happen outside the operating room, although they are still poor, with a "viable" survival of only about 25%.[82] It is important, therefore, that patients be informed of the risks and benefits of cardiac resuscitation so that they can best determine whether to ask for their DNAR order to be suspended during the perioperative period.

Although the patient's primary care physician may have introduced the idea of DNAR orders to the patient or the surrogate decision maker, it is the anesthesiologist's duty to discuss the risks and benefits of resuscitation in the setting of anesthesia and surgery before undertaking the patient's care. The anesthesiologist should include in this discussion the following steps: (1) determine the patient's goals regarding surgery and resuscitation; (2) establish exactly what is meant by "resuscitation," in contrast to routine anesthetic care; (3) educate the patient about the risks and benefits of resuscitation in the operating room setting; and (4) document the agreements reached with the patient about which interventions commonly associated with resuscitation are acceptable to him or her. Such interventions could include, but are not limited to, intubation, administration of vasoactive drugs, administration of direct current countershock, and institution of chest compressions. Many patients who express reluctance about resuscitation during surgery actually most fear burdensome collateral outcomes, such as permanent neurologic impairment, rather than the process of resuscitation itself. Education and discussion may reassure these patients about the potential outcomes of resuscitation in the operating room and can establish ground rules for discontinuing interventions postoperatively if they do not lead to a chance of meaningful recovery.

Surgery depends on the cooperation of many caregivers with differing expertise, each with independent ethical obligations to the patient. Resuscitation agreements must be discussed with other members of the operating room team. This communication prevents crucial disagreements from occurring during a critical event when treatment decisions must be made quickly. It also allows "conscientious objectors" to withdraw from the healthcare team.

Advance directives are legally and ethically binding. Despite clear, consistent, and forceful legal decisions, physicians have ignored DNAR directives under the false assumption that the legal authority of advance directives and living wills is not binding in the operating room or that the physician has discretion in deciding when to follow or ignore such directives—and families have sued for significant monetary damages for the costs of continued health care and punitive damages for the pain, suffering, and mental anguish of the patients' survivors when DNAR instructions are ignored.[83,84]

In 1990, the U.S. Congress passed the Patient Self-Determination Act that recognizes a competent patient's right to refuse any medical therapy, including life-sustaining therapy, and requires medical institutions and providers to advise patients of these rights and ask about their preferences.[76] Compliance with the act is required in order to participate in Medicare and Medicaid reimbursements. Furthermore, in 2006, the American Civil Liberties Union filed suit against a group of New Mexico orthopedic surgeons who were requiring patients to sign away their rights to DNAR as a requirement of surgery, arguing that this not only violated the 1990 Patient Self-Determination Act, but denied patients their constitutional rights. The surgeons were required to desist in that practice, publicize the change in policy (to respect DNAR), and pay attorneys' fees and various other fines.[85]

Finally, DNAR orders must never be construed as an excuse to not "care" for the patient. A patient's decision to forgo resuscitation does not imply a wish to avoid other beneficial interventions. Placement of a pulmonary artery catheter, for example, may help ensure optimal management of a frail patient who has a DNAR order and enable the anesthesiologist to avoid situations in which the patient's DNAR status becomes pivotal.

END-OF-LIFE DECISION MAKING

A 1996 review by the AMA showed that the following end-of-life issues were of foremost importance to patients: control over the timing and location of death; management of symptoms such as pain, dyspnea, anxiety, and depression; financial management of medical care; and maintenance of therapeutic options, including physician-assisted suicide (PAS).[86]

Withdrawal or Withholding of Medical Therapies

Between 2000 and 2010, about one-third of deaths in the United States occurred in short-stay general hospitals.[87] Patients and doctors alike recognize that aggressive medical therapy may not be desired or even appropriate in the presence of advancing disease, and over time the use of hospice and palliative care facilities has increased.[88] Most deaths in ICUs occur after an explicit decision to withdraw or withhold treatments.[89]

Before the mid-20th century, the concept of beneficence in the eyes of physicians was strongly tied to preventing death. Ethical distinctions between acts of omission ("letting die") and acts of commission ("killing") were and remain confusing at best. Worse, physicians faced threats of criminal punishment if a patient's death resulted from withdrawal of medical treatments.[90] In 1976, the case of Karen Ann Quinlan established that patients have a right to forgo invasive treatments, even if lifesaving, and that surrogate decision makers could ask for withdrawal of lifesaving therapies if the surrogates could show that the patient would not have wanted them.[91] The right to forgo lifesaving treatments was later extended in the cases of Claire Convoy and Nancy Cruzan to include *any* treatment if the patient refused it or if clear and convincing evidence indicated that the patient would have refused therapy if he or she could speak for himself or herself.[76] These decisions were revisited and reconfirmed in the tragic case of Theresa Schiavo in 2005.[92]

Arguments that withdrawing or withholding life-sustaining therapy does not violate rules against killing patients are based on ethical differences between killing and letting die, and between acts of commission (e.g., lethal injection) and acts of omission (e.g., withdrawal or withholding of ventilator therapy).[93] Because such distinctions are confusing to both physicians and patients, a *principle of proportionality* is often applied when withholding or withdrawing treatments.[94] In this principle, treatment is indicated to the extent that it is likely to present more benefits than burdens to the patient based on the patient's perception of such medical, social, and psychological benefits and burdens. Of course, competent patients still always have the right to refuse therapy, even if lifesaving and otherwise indicated.

Two common settings in which anesthesiologists may be involved in withdrawing or withholding life-sustaining interventions are the ICU and the operating room before organ donation after cardiac death (DCD). In both cases, the issues and principles of withdrawing or withholding treatments are the same.

Withdrawal of life-sustaining interventions heralds the final phase of end-of-life care, and it is a socially critical phase in the life of the patient and family. Terminal care requires special knowledge and experience on the part of the physician. It requires expertise in medically supportive therapy, management of problematic symptoms, knowledge about physiologic changes in the dying patient, support and counseling of patients and families, understanding and respect for the patient's autonomy and religious and cultural practices and beliefs, the ability to work within complex healthcare teams, the ability to communicate well, and empathy. Anyone intimately involved in care of the dying patient should also be intimately familiar with ethical and legal standards.

Withdrawal of life-sustaining treatment begins with an assessment of the individual patient's physiology, level of dependence on therapy, degree of consciousness, preferences regarding sedation and analgesia, and preferences regarding privacy and level of involvement of family and other loved ones. All the patient's treatment orders should be reviewed to meet the new treatment goals. Treatments promoting the patient's comfort should generally be continued, whereas those directed only at physiologic maintenance may all be withdrawn. Family members and others attending the patient at the end of life should be educated about physical and mental changes they can expect to see as treatments are scaled back, including the possibility that death will not occur imminently once support is withdrawn.[95]

Several interventions have ethical implications and deserve special consideration—fluid and nutritional management; the administration of sedatives and narcotics that have the potential to hasten death; the administration of neuromuscular blocking drugs; and deactivation of pacemakers, ventricular assist devices, and implantable cardioverter-defibrillators (ICDs).

The issue of fluid and nutritional support is controversial. Burdens associated with continuation of fluid and nutritional support include prolongation of the dying process, and complications and suffering from placement and maintenance of intravenous or enteral access (or both). However, feeding and hydration may have important connotations for family members and members of the healthcare team by allowing a sense of nurturing and mitigating feelings that they are "abandoning" the patient.[95]

Pain, dyspnea, and depression are all common symptoms that cause suffering in the dying patient. Alleviating pain and dyspnea carry the risk of hastening death. Medical, legal, and religious authorities have all clearly accepted the principle of "double effect," in which an action intended to produce a benefit for the patient produces not only the expected benefit but also the potential for significant harm. It is entirely ethical and legal to administer high doses of pain medication and sedatives for the intended effect of relieving suffering, even if the treatment has the side effect of hastening death. However, to administer any medication with the explicit intention of hastening death is euthanasia, and not medical therapy.[95]

TERMINAL SEDATION

"Terminal Sedation," also known as "deep continuous sedation" (DCS), is an ethically controversial end-of-life strategy for patients who are suffering intolerable symptoms in the last stages of dying, and who do not respond well or completely to sedatives or pain medications that are being administered "as needed" in response to symptoms. In DCS, a decision is made with the patient or their appropriate surrogates to forgo reactive treatment of symptoms and to employ intravenous sedative/analgesic infusions with the intention of rendering the patient permanently unconscious until death occurs, but without the intention of causing death. While the goal of DCS—relief of suffering—is a laudable one, ethical questions nevertheless persist: the practice is plagued by vague and nonstandardized terminology and practice, a lack of outcomes research, an uncomfortable confusion with PAS and euthanasia, misunderstanding of the principle of double effect, and culturally diverse philosophies about the role of suffering and transcendence in the meaning of human life.[96] Opponents suggest that DCS is merely euthanasia in disguise, invented to circumvent legal sanctions and moral objections. Some ethicists have argued that DCS permanently deprives the patient of morally relevant aspects of "personhood" and therefore represents a form of killing. Disturbing studies show that many physicians employing DCS actually *do* intend to hasten death.[97,98]

A particularly controversial aspect of DCS is whether it can and should be allowed when the patient is suffering from severe and intractable *existential* suffering: fear, loneliness, anxiety, spiritual crises, and so forth. Professional guidelines regarding DCS and existential suffering at end of life differ greatly in their recommendations: the American Academy of Hospice and Palliative Medicine[99] and the American College of Physicians[100] do not make specific statements about DCS in existential suffering; the AMA Council on Ethical and Judicial Affairs opposes DCS for existential suffering;[101] the Royal Dutch Medical Association[102] and the Harvard University Community Ethics Committee[103] support the use of DCS in cases of existential suffering; and the Veterans Health Administration does not exclude it, but weighed against use of DCS for existential symptoms in their discussions.[104] Even more questions arise when DCS is instituted in pediatric patients.[96]

NEUROMUSCULAR BLOCKING DRUGS

Neuromuscular blocking drugs have no anesthetic, analgesic, or sedative properties. Such drugs should not be initiated if withdrawal of ventilatory support is anticipated. Paralyzing the patient to comfort *the family* so that they see no disturbing movements or respirations as the patient dies is not justifiable. Even worse, it can mask symptoms and signs of distress and can thus prevent relief of suffering during the dying process.[95] When withdrawal of ventilator support is anticipated in a patient already receiving such drugs, they should be withheld in all but extraordinary cases.[105,106]

IMPLANTABLE CARDIAC DEVICES

When a patient who has a cardiac device requests withdrawal of life-sustaining interventions, questions can arise about whether it is ethical to deactivate or even explant such devices at the patient's request. In the case of ICDs, the question might well be whether it is ethical to *continue* such therapy in a patient who has opted for palliative care. Recent studies provide concerning information: in the MADIT II trial, only 15% of patients who died had their ICD deactivated, after receiving "many" shocks at the last days of their lives.[107] A post-mortem device interrogation study indicates that 31% of patients received shocks in the last 24 hours of life.[108] It is likely that patients receiving shocks in the final hours of their lives may be unable to communicate that they are suffering this painful experience and ask to have it stopped. In another study, only 27% of patients had discussed deactivation of the ICD at end-of-life,[109] raising concerns that failure to deactivate the device was due largely to failure of physician-to-patient communication that this was possible and should be considered. In some cases, physicians may lack the expertise or equipment to promptly deactivate such devices when inappropriate shocks are being delivered.[110]

Some experts have said that that these devices must be treated differently from other medical interventions because by virtue of implantation they have become a "biofixture," or literally a part of the patients themselves.[111] Such arguments are difficult to sustain when we consider that many people undergo implantation of medical devices and subsequent explantation of them when the devices are no longer working or do not serve the patient's purpose. Common examples include artificial joints, intraocular lenses, medication delivery devices, and orthopedic hardware. Furthermore, these devices are never uniquely a part of the patient in the same sense as DNA or their native organs. In fact, the ethical distinction between disabling a pacemaker in a pacer-dependent patient and turning off a ventilator for a ventilator-dependent patient is minimal if the request comes from a competent patient or the surrogate decision maker. Both actions involve discontinuance of artificial therapies that the patient no longer desires, and both may be followed by rapid death.

Consensus statements and guidelines by the Resuscitation Council of the UK, British Cardiovascular Society, and National Council for Palliative Care,[112] the European Heart Rhythm Association, and Heart Rhythm Society,[113] and the Canadian Cardiovascular Society[114] all recommend discussion with the patient of deactivation of implantable cardiac devices in end-of-life care.

The presence of a do-not-resuscitate order should not be taken as an automatic request by the patient to discontinue implantable device therapy. As with other end-of-life therapies, discontinuance of such devices should include due consideration of whether the decision is made by a competent patient and with full informed consent. Management of discontinuance of device therapy should always include planning for treatment of distressing symptoms and administration of appropriate comfort measures.

PHYSICIAN-ASSISTED SUICIDE AND EUTHANASIA

PAS is defined as the provision of medication or prescriptions by a physician to a patient at their specific request for the explicit purpose of ending their life. PAS requires a patient who is both competent and capable of communicating the request, as well as capable of self-administration. Euthanasia is defined as the administration of medication by someone other than the patient for the express purpose of causing death in the belief that this would be best for the patient, but not necessarily at the specific request of the patient. Both practices differ ethically from withdrawing or withholding life-supporting medical treatments. In withdrawal or withholding of life-supporting treatment, the primary intention is to discontinue treatments that are causing suffering with an understanding that death may or probably will result. In PAS and euthanasia, the primary intention is to cause death, which secondarily ends suffering.

Currently, euthanasia is legal only in the Netherlands, Belgium, and Luxembourg. Some confusion exists about the status of euthanasia in Colombia, which has been labeled as allowing "euthanasia," but appears in fact to have legalized PAS, reflecting a common misconception in the press about differences between the two practices.[115] In the United States, euthanasia remains illegal regardless of circumstance, but PAS is legal as of 2018 in the states of Oregon, Washington, Montana, Vermont, Colorado, California, and the District of Columbia. It narrowly missed ratification in New Mexico after being passed by both state houses in 2017, and it passed the Hawaii State House of Representatives in March of 2018. It is also under consideration in other states. Thirty-seven states have specific laws that make PAS illegal, and four states have no specific laws regarding PAS.[116] Internationally, PAS is legal only in the Netherlands, Belgium, Luxembourg, Germany, and Switzerland.[117]

Supporters of PAS argue that the right to privacy and respect for autonomy support a patient's right to determine the time, location, and circumstance of his or her own death. Patients consistently rate loss of autonomy and control, inability to pursue previously valued activities, and loss of dignity as the major concerns at the end of life. Adequate control of pain, anxiety, dyspnea, and other symptoms at the end of life remain a challenge to the medical profession, thereby fueling the desire for a means to end life when suffering cannot be controlled. Opponents argue that PAS "medicalizes" death, overly idealizes the physician-patient relationship, ignores possible personal and professional conflicts of interest, and leads to erosion of trust between dying patients and their doctors. Although many ethicists acknowledge that individual circumstances may make assisted suicide an ethically permissible action, most express concerns about potential abuse. Vulnerable members of society, such as the poor, old, and handicapped, could be pressed by financial and social factors into a suicide option in preference to palliative care. An additional argument against PAS or legalized euthanasia is that these approaches could provide solutions to the medical, social, and economic problems common to older and poor patients that are simpler and less expensive than seeking and requiring more difficult but definitive remedies.

Twenty years have passed since Oregon legalized and enacted PAS in 1997 and the Netherlands legalized both PAS and euthanasia, and significant data now provide some insights into whether these concerns about PAS and euthanasia are materializing. In recent polls, more than two thirds of the U.S. population polled favored legalizing PAS, and approximately 70% favored legalization of euthanasia.[118] The percentage of U.S. oncology patients favoring a PAS or euthanasia option in end-of-life care is approximately 65%,[119] whereas physicians frequently involved in end-of-life care, such as intensive care specialists, oncologists, and palliative care specialists, are the most uniformly opposed specialists.[120] This finding represents a significant discordance between physicians and their patients.

In Oregon, where PAS has been legalized for the longest period in the United States, data from 2015 (the most recent year available) remain consistent and show that patients who requested PAS were more likely to be white and had generally higher economic status and education. More than 99.2% were insured, and 92.2% were enrolled in hospice care. Most were more than 65 years old (78%), and 72% were suffering from cancer. As of 2015, 36% of patients receiving prescriptions for PAS (a total of 1545 patients over 20 years) never used them and ultimately died of their underlying disease—with many surviving significantly longer than predicted. More than 92% of patients enrolled in the Oregon program cited loss of autonomy as a primary reason for pursuing the option.[121] Some authors have suggested that the possession of a means to end their lives legally and humanely prevented "preemptive" suicides that could have occurred earlier and thus may have prolonged lives.[122]

Concerns regarding abuses of PAS and euthanasia will undoubtedly continue, but thus far, evidence of systematic abuse is lacking in places where PAS is legalized and regulated. As the population ages and patients desire greater control over end-of-life care and circumstances, debate over PAS and euthanasia in the United States can be expected to continue to grow.

ETHICAL ISSUES IN ORGAN TRANSPLANTATION

Two issues critical to vital organ transplantation that confront anesthesiologists are the concept of brain death and the linkage of withdrawal of life-sustaining therapies with organ retrieval and transplantation after cardiac death (DCD).

Brain Death

Before the 1960s, death was defined as the moment when the heartbeat stopped and respirations ceased. Advances in cardiopulmonary resuscitation and mechanical ventilation then made it possible to postpone death, seemingly indefinitely. In 1968, the Ad Hoc Committee of the Harvard Medical School proposed redefining death as the point at which all cardiorespiratory function had irreversibly ceased, *or* all function of the whole brain had irreversibly stopped (brain death).[123,124] The committee gave two explicit reasons for redefining death. The first was to allow patients to be declared dead and not maintained on machines—thus limiting expense; reallocating medical resources to other, salvageable patients; and allowing the social rituals surrounding death to occur. The second was to allow the donation of vital organs before circulation stopped.

Declaration of death further carries nonmedical consequences, such as the process of mourning, initiation of any criminal prosecutions, inheritance, taxation, and burial concerns. It was thus considered important that determinations of death follow consistent rules across state boundaries, and the National Conference on Uniform State Laws issued the Uniform Definition of Death Act in 1980, which was adopted by the states.[124]

The public has been slow to accept brain death, in part because it requires complete trust in physicians and ignores indicators of death that the public already understands. To nonphysicians, brain-dead donors are superficially indistinguishable in many ways from living persons, and nonphysicians must therefore rely completely on the physician for both accurate and honest information of a loved one's death. Recent court cases challenging declaration of death in patients who clearly did meet standard brain death criteria, such as that of Aden Hailu in Nevada, illustrate continued public uncertainty.[124]

Medical standards in diagnosing brain death are relatively straightforward, although variations in the definition of death itself persist throughout the United States.[124] In the United States, medical standards require demonstration that, in the absence of drugs, paralytic agents, hypothermia, and other reversible conditions that mimic loss of brain function, no cortical or brainstem function is present. The diagnosis is usually made either clinically, by demonstrating that cortical activity and brainstem reflexes are absent, or by radiographic studies demonstrating the complete absence of cerebral blood flow.

Although brain death is a *social* and not a *biologic* definition of death, medical, ethical, theological, and legal experts generally agree that brain death adequately defines a condition in which a person with ethical and legal rights and moral standing ceases to exist and should no longer be treated as though alive. Expensive medical interventions can be discontinued without legal ramifications, and vital organs can be donated for transplantation if the patient or the surrogate decision maker agrees.

Before assuming care of a brain-dead organ donor, the anesthesiologist is obligated to review the chart for documentation of the declaration of brain death and the criteria on which it was based. If any questions exist about the diagnosis, organ donation should be postponed until the anesthesiologist is satisfied that these concerns are addressed.

Donation after Cardiac Death

DCD occurs when a patient wishes to have life-sustaining medical therapies withdrawn and also wishes to proceed with vital organ donation after death. Controlling the time and place of death so that timing of organ donation can be optimized has obvious medical and ethical advantages. The decision to donate organs is made before death, thereby allowing time for discussion and informed consent. Organ ischemia time can be minimized. The dual decision to withdraw life-sustaining interventions and donate vital organs after death can create ethical conflicts, however. When a dying patient becomes an imminent organ donor, the risk is that the patient's interests will be minimized or ignored in favor of the organ recipient.

The National Academy of Medicine reviewed DCD in 1997[125] and 2000[126] and found serious ethical questions, such as determining how quickly after asystole organ donation can begin and whether medications can ethically be administered to the donor before death that are solely for the purpose of organ preservation.

Ethical, theological, and legal principles prohibit us from killing one person to benefit another, but the point at which actual death has occurred in DCD donors is unclear. Although expedient donation is the very purpose of DCD, doctors must never sacrifice any living patient in the process or even take significant risks of doing so; the mistrust this would engender among the public could place the entire concept of DCD at risk by reducing potential donors and ultimately harming future potential organ recipients.[127] Loss of consciousness occurs quickly after asystole, but brain function can continue for some time, and irreversible brain injury may not occur for many minutes. Yet some protocols call for organ retrieval to begin only 2 minutes after circulation has stopped, and in at least one institution, organ harvest is allowed to begin within seconds of cardiac arrest.[128] Scientific and philosophic uncertainty exists about when death is complete—this could even lead to accusations that physicians deliberately kill patients to obtain organs for transplantation. Mistakes have occurred in some cases of brain-dead organ donors for which clear clinical criteria exist; DCD organ donation is potentially even more prone to error because no such clinical guidelines are universally accepted.[129]

Donation of vital organs after brain death and DCD are both ethical and legal, but the interests of the dying patient must be absolutely protected until after death has occurred. Anesthesiologists can play a vital role in the organ donation process by helping hospitals develop reasonable and ethical policies for the management of brain-dead donors and DCD donors. Every anesthesiologist should be thoroughly familiar with brain death criteria and should review the process of brain death determination before accepting care of a brain-dead donor. It is inappropriate for anesthesiologists to be involved in organ DCD unless they have expertise in the relevant ethical, legal, and medical issues and are experienced in end-of-life care.

Research Ethics

HUMAN SUBJECT RESEARCH

The premise that the physician always puts the best interests of the patient first can be jeopardized when research objectives enter the doctor-patient relationship. Human subjects are asked to put aside their own interests to benefit some future, hypothetic group of patients. In extreme cases, the patient becomes a research "object" who will not benefit personally from the experiment at all. Two examples include experiments in healthy subjects and phase I cancer trials in terminally ill patients in which the goal is to determine the toxicity of treatment—not remission, palliation, or cure.

Human subject research must balance many conflicting interests, such as the needs and rights of the research subject, the hypothetic interests of future patients, and the physician's financial, professional, and personal goals. Academic or corporate advancement, personal prestige, and financial incentives may be disincentives to researchers who diligently protect patients' interests or who remain objective in designing protocols and analyzing and reporting their findings. Thus, human subject research is more closely regulated, supervised, and controlled than any other medical endeavor.

Regulation of research began after World War II, with the Nuremburg Code and the Helsinki Declaration outlining the ethical obligations of physicians engaged in human research. The United States was slow to awaken to the parallels between the concentration camp experiments and the sometimes gruesome treatment to which they subjected their own subjects in similar trials.[130] In the years that followed the Doctors' Trial at Nuremburg, Fox[131] and Beecher[132] found that researchers were aware of the standards set at Nuremberg but regularly did not comply with them. In 1974, the National Research Act established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, out of which the modern institutional review board was born.

The ethical conduct of human subject research follows three principles: (1) respect for autonomy and the obligation to protect subjects with limited autonomy; (2) beneficence, with obligations to minimize risks, maximize benefits, and ensure that the research design is scientifically sound; and (3) justice, the obligation to treat each person with regard to what is morally right and to ensure fair distribution of benefits and burdens.

In addition to the comprehensive presentation to research subjects of the risks and benefits of procedures or medications to which they will be subjected, disclosure must include the possibility of commercialization of the results, financial interests of the researchers, and any other actual or perceived conflicts of interest on the part of researchers and their institutions and sponsors. Subjects must be free to refuse or end participation at any time without penalty. *Situational coercion,* in which subjects feel that they are not truly free to refuse, should be avoided or mitigated. Examples of situational coercion include prisoners whose terms and experiences of incarceration may be affected by their decision to participate or refuse, and hospitalized patients who may believe that their care could be compromised if they do not cooperate with researchers.[130]

Monetary or other inducements to participate in research are probably permissible if they do not undermine the freedom of the subject to refuse under reasonable circumstances. Significant monetary awards may have adverse effects on the autonomy of subjects and may negatively affect the scientific quality of the research. If remuneration is high, for example, subjects could conceal factors that would otherwise disqualify them from participating, thus compromising the research results and exposing themselves to greater risks.

Researchers are obligated to maximize benefits and minimize potential harms, including physical, psychological, social, legal, and financial harms. The research must address a question of significant value to justify the level of risk and must follow the approved protocol. Findings must be promptly and accurately reported. The research must be terminated immediately if it is suspected to be harmful to the participants.

Anesthesiology research often involves the treatment or prevention of unpleasant symptoms, such as pain and nausea. When effective treatments are well established, such studies should be restricted to comparison of treatments with known efficacy, not placebo-controlled trials, and "escape" analgesics or antiemetics must be provided on the patient's request.

No population group should be unfairly subjected to research without having equal access to its benefits. Finally, the interests of the individual must always prevail over the interests of society.

Children as Research Subjects

Children are particularly vulnerable as research subjects because they may lack the ability to make mature decisions, are subject to the authority of others, may defer to their parents and others in ways that mask underlying dissent, and may have conditions requiring immediate decisions not consistent with informed consent.[133] Children's rights are frequently undervalued, whereas parental authority may be overvalued. Studies show that even children with decision-making capacity are often excluded from the consent process by both parents and physicians.[134]

If a minor child is "able" to assent, then assent must usually be obtained in addition to the consent of any legal surrogate decision makers. In the United States, federal law requires assent of any minor age 7 years and older to participate in medical research. Particularly for research in which no substantive individual benefit is expected, many ethicists believe that a child's dissent *must always be honored.*[134,135]

ETHICS OF ANIMAL RESEARCH

The animal rights movement in the United States has gained significant momentum since the 1980s, following in the wake of the U.S. civil rights movement and paralleling increasing awareness and concerns about the human impact on the environment and other animal species. In 1959, William Russell and Rex Burch published their sentinel book regarding the ethics of animal research, *The Principles of Humane Experimental Technique*, introducing the concept that humane treatment of animals was not merely an ethical imperative, but absolutely necessary to high-quality research.[136] Federal legislation protecting animal welfare began with the Laboratory Animal Welfare Act of 1966. In 1985, the Health Extension Act and amendments to the Animal Welfare Act required the establishment of Institutional Animal Care and Use Committees, which oversee conditions of laboratory animals; review and approve animal research protocols; educate and train investigators in ethical issues and aspects of animal handling such as anesthesia, analgesia, and euthanasia; and act as community liaisons.

Some researchers deny that animal experimentation could be subject to any moral reservations and assert that medical advances have been and continue to be completely dependent on continued animal research. Many animal welfare activists insist on the moral equivalence of animal experimentation to that of human experimentation and accuse researchers of being blind to or, even worse, actually unmoved by the suffering of animal subjects. The simplicity of these polarized views does not do justice to the complexity of the issues.

Advances in the understanding of animal cognition led most biologists to believe that many, if not all, animals are capable of feeling pleasure, pain, anticipation, and fear, and thus experience both enjoyment and suffering. Many bioethicists state that the higher animals therefore have adequate awareness to possess moral standing, although how much moral standing is intensely debated.[137,138] Allowing animal suffering as a result of pain, fear, sickness, or poor standards of care is a moral harm that must be avoided, mitigated, and weighed heavily against the benefits it produces. Ethicists maintain that cruelty to animals is immoral and that animals should be protected from it, not merely because they have moral standing, but because he who is cruel to animals is more likely to be cruel to humans.[139]

Researchers have obligations to provide clean and humane conditions and appropriate veterinary care for animal subjects. Researchers should mind the "Three Rs"—replacement, reduction, and refinement—that is, use animal subjects only when necessary, minimize any suffering incurred in the study, and seek nonanimate replacements for animal subjects.[99] Mediocre or repetitive research using animal subjects should not be allowed. It is the responsibility of the medical and scientific community to continue aggressively to seek and promote alternatives to the use of animal subjects.[139]

PHYSICIAN PARTICIPATION IN EXECUTIONS

U.S. professional organizations for physicians have consistently stated that physicians' participation in executions is unethical, yet many physicians admit that they would agree to be involved. The role of physicians in euthanasia and executions is of particular concern to anesthesiologists, who have been identified as ideal candidates for duties that involve killing because of their particular professional skills. Arguments in favor of physicians' involvement in executions usually cite the principle of beneficence in allowing a humane death.

Historically, however, beneficence arguments have led to "slippery slope" justifications for physicians to be involved in the killing of persons who have never faced an accuser or had a fair hearing—such killings have included persons with physical or mental handicaps and other "social flaws" for the "benefit" of the individual and of society as a whole. Once physicians accept a beneficence argument for participating in executions, it is difficult ethically to draw the line at participating in other state-sponsored activities, such as torture, coercion, and "medical incarceration," because these activities are also usually defended as being beneficial to society.[140]

When physicians agree to participate in an execution, they act as agents of the state while appearing to act on behalf of the "patient." This situation can lead to eventual erosion of public trust and respect. It also at times undoubtedly leads to physicians' participation in the killing of innocent persons.[141]

To avoid intolerable self-condemnation, virtually all executioners undergo "moral disengagement" in which they dehumanize the convicts and devalue their lives, thereby deflecting moral responsibility for the execution away from themselves by blaming juries, judges, governors, and "the law" rather than accept the responsibility they share in ending the prisoner's life.[142] It is difficult to reconcile the medical profession's overt ethical imperatives of valuing human life, respecting individuals, and accepting personal moral responsibility with participation in a process that requires a rejection of these very values.

In 1980, the AMA issued an opinion that physicians' involvement in capital punishment is unethical and defined "participation" broadly as including not only actions that themselves would lead to the death of the condemned but also any activity that assisted, supervised, or contributed to another's being able to do so.[143] However, no direct sanctions of any participating physician were addressed. In 2010, the American Board of Anesthesiology became the first organization of physicians not only to condemn participation in capital punishment as unethical but also to state that physicians who were certified by their board and who participated in lethal injection would be subject to disciplinary action that could include revocation of their diplomate status.[144]

MORAL INTEGRITY—CAN THE PHYSICIAN BE A CONSCIENTIOUS OBJECTOR IN MEDICINE?

Anesthesia care of patients can involve ethical controversy, legitimate disagreement, and moral ambiguity. How a physician resolves moral conflicts when their personal values run counter to acceptable ethical standards of care is a matter of much concern.[145,146] Medical professional societies recognize the right to conscientious objection in medical practice. The ASA, the British Medical Association, and the bioethics research institute, The Hastings Center, all have issued statements recognizing the physician's right to withdraw from situations in which ethical standards of patient care are in serious conflict with his or her personal values.[147] The ASA specifically recognizes conscientious withdrawal from patient care in the case of patients with DNAR orders or other directives that limit treatment.[25] These rights have limitations, however. Acceptance of moral objections to certain hotly contended issues such as abortion or PAS may be reasonable, but objections to well-established standards, such as informed consent, are not. Moral objections of physicians are also likely to carry more weight if they involve concepts that the physician believes supports him or her as an ethical doctor, and not just as an ethical person, because these concepts are more likely to be founded in professionally established standards than in personal beliefs.[147] When physicians' personal religious and other moral beliefs are allowed to supersede those of patients, the result has almost uniformly been barriers in health care to vulnerable groups, such as women, adolescents, and the elderly.[148,149]

In early 2018, the U.S. Department of Health and Human Services moved under conservative political leadership to strengthen doctors' rights to refuse to refer patients for legal medical treatments that they personally object to, such as abortion, transgender treatments, and birth control, for example. The AMA has raised concerns that the move both combines and illegally broadens laws that have not been subjected to public vote. Dr. Lainie Friedman Ross, physician and ethicist at the University of Chicago, points out that "it is very problematic because it forgets that doctors are powerful individuals and patients are vulnerable. The law is all about protecting doctors, not the individuals who need the protection—those who are sick and frightened."[150] It remains to be seen whether the new rules will withstand inevitable legal challenges. In the meantime, a Canadian court ruled in the opposite direction, that the requirement to refer patients to legal medical treatments in Ontario was "a reasonable limit on the religious freedom of doctors, necessary to prevent harm and inequitable access for patients."[150]

Consciousness, Memory, and Anesthesia

GEORGE A. MASHOUR and KANE O. PRYOR

KEY POINTS

- Mechanisms of consciousness and memory, and their interruption by general anesthetics, are important scientific problems that have clinical relevance for the practice of anesthesiology.
- Consciousness is characterized by both wakefulness (i.e., the brain being aroused) and awareness (i.e., subjective experience).
- Anesthetics act at structures in the brainstem, hypothalamus, and basal forebrain that regulate sleep-wake states, which may account for loss of wakefulness.
- Anesthetics disrupt connectivity and communication across cortical and thalamocortical networks, which may account for loss of awareness.
- Memory can be subdivided into explicit (conscious) and implicit (unconscious) recall; an example of explicit episodic recall is remembering a surgical event.
- Suppression of explicit episodic recall is one of the most potent effects of most general anesthetics.
- Effects on the hippocampus, amygdala, and prefrontal cortex—as well as the connectivity of these structures—may account for anesthetic-induced amnesia, even before loss of consciousness.

Introduction

SCIENTIFIC AND CLINICAL IMPORTANCE

Consciousness and memory are among the most fascinating and complex subjects in all of science. The richness of human consciousness and memory—and the ability to express this richness in language—is a defining characteristic of *homo sapiens*. Consciousness and memory also have clinical relevance for the anesthesiologist; together, the experience and explicit episodic recall of surgical events is known as the problem of "intraoperative awareness." When formally assessed, this complication occurs in approximately 1 to 2 cases per 1000[1-3] and is associated with a high incidence of posttraumatic stress disorder (PTSD).[4,5] The incidence of intraoperative consciousness without recall is substantially higher.[6] To advance the field of perioperative brain monitoring, a detailed understanding of the neurobiology of consciousness, memory, and anesthesia is required.

Consciousness

DEFINITIONS

The field of consciousness studies has been plagued by the indiscriminate use of the term "consciousness." When we refer to consciousness, we mean *subjective experience*. In simple terms, it is what we lose when we have dreamless sleep and what we regain again in the morning upon awakening. There are, however, several important definitions and distinctions that should be considered.

1. **Awareness**: Cognitive neuroscientists and philosophers use the term "awareness" to mean *only* subjective experience. In clinical anesthesiology, we (inaccurately) use the term "awareness" to include *both* consciousness *and* explicit episodic memory[7] (the taxonomy of memory will be discussed in the next major section of the chapter).
2. **Connected versus disconnected consciousness**: Connected consciousness is the experience of environmental stimuli (such as surgery), whereas disconnected consciousness is an endogenous experience (such as a dream state).[8]
3. **Consciousness versus responsiveness**: An individual may fully experience a stimulus (such as the command "Open your eyes!") but not be able to respond (as when a patient is paralyzed but conscious during surgery).[9]

There have been a number of theories proposed to explain the mechanisms of consciousness and general anesthesia. Advances in neuroscience, however, have enabled us to move beyond speculative frameworks and focus on a systems-based approach to both subjects.[10] The remainder of this section on consciousness adopts such an approach by discussing (1) brainstem and hypothalamic nuclei regulating the sleep-wake cycle (and therefore arousal states) (Figs. 9.1 and 9.2); (2) the role of the thalamus in consciousness and anesthesia; (3) cortical-subcortical connectivity, with a focus on the thalamocortical system, which is thought to mediate the experiential component of consciousness; and (4) cortico-cortical communication.

Fig. 9.1 Neurobiology of wakefulness. Multiple neurochemical systems in subcortical regions (shown here in rodent brain) promote arousal and activation of the cortex. Monoaminergic neurons *(light green)* in the rostral brainstem and caudal hypothalamus innervate the cortex as well as many subcortical regions including the hypothalamus and thalamus. These monoaminergic regions include noradrenergic neurons (locus coeruleus), serotonergic neurons (dorsal and median raphe nuclei), dopaminergic neurons (ventral tegmental area), and histaminergic neurons (tuberomammillary nucleus). Wake-promoting signals also arise from cholinergic regions *(dark green with hatching)*, including the pedunculopontine and laterodorsal tegmental nuclei and basal forebrain. General anesthetics have been demonstrated to suppress many of these regions. (Redrawn from Scammell TE, Arrigoni E, Lipton JO. Neural circuitry of wakefulness and sleep. *Neuron.* 2017;93[4]:747–765.)

GABA-ergic neurons in the ventrolateral preoptic area and median preoptic nucleus in the hypothalamus (shown here in rodent brain) promote sleep by inhibiting wake-promoting neurons in the caudal hypothalamus and brainstem. These hypothalamic nuclei are activated by general anesthetics. (Redrawn from Scammell TE, Arrigoni E, Lipton JO. Neural circuitry of wakefulness and sleep. *Neuron.* 2017;93[4]:747–765.)

SUBCORTICAL NUCLEI REGULATING AROUSAL

It was hypothesized in the mid-1990s that anesthetics suppress consciousness by actions at the subcortical nuclei that evolved to control sleep-wake cycles.[11] The past decades have supported the hypothesis that anesthetics interact with a number of these sleep-wake centers,[12,13] although precise interactions and contributions to the state of general anesthesia have yet to be elucidated. The following is a description of select subcortical nuclei in the brainstem and hypothalamus that mediate sleep-wake cycles[14] and, potentially, some traits of anesthesia.

Brainstem

Locus ceruleus. Norepinephrine is synthesized in the locus ceruleus (LC), which is located in the pons and projects widely throughout the cortex.[15] Like other monoaminergic neuronal populations, LC activity is highest during waking consciousness, decreased during nonrapid eye movement (NREM) sleep, and at its nadir during rapid eye movement (REM) sleep.[16,17] Thus LC is associated with cortical arousal only during wakefulness and not with the cortical activation during REM sleep. LC neurons are hyperpolarized by halothane.[18] The role of norepinephrine (generated by LC) in anesthesia is further supported by studies demonstrating that barbiturate anesthesia time is increased by antagonizing norepinephrine and reduced by agonizing it.[19,20] Norepinephrine transmission in the basal forebrain may be of particular relevance to anesthetic depth.[21] It has been found that LC noradrenergic neurons modulate the state of isoflurane anesthesia as well as emergence therefrom.[22] Of note, administration of ketamine is associated with an increase of activity in the LC[23] and appears to contribute to its anesthetic effects.[24]

LC and the role of norepinephrine in hypnosis are of particular interest due to the role of the α-2 agonist dexmedetomidine in clinical care. Microinjection of dexmedetomidine in the LC results in reduced levels of consciousness that can be prevented by coadministration of the α-2 antagonist atipamezole.[25] After exposure to dexmedetomidine, brain changes somewhat mimic NREM sleep in that the LC and tuberomammillary nucleus (TMN) are deactivated, whereas the ventrolateral preoptic nucleus (VLPO) is activated.[26] Data in dopamine-β-hydroxylase knockout mice (which lack the ability to synthesize norepinephrine) demonstrate a *hypersensitivity* to dexmedetomidine, suggesting alternative mechanisms of action.[27] However, selective knockdown of α-2A adrenergic receptors from LC prevent dexmedetomidine-induced loss of righting reflex,[28] a marker of general anesthesia in rodents.

Laterodorsal/pedunculopontine tegmentum. Along with the basal forebrain, the laterodorsal tegmentum (LDT) and pedunculopontine tegmentum (PPT) in the pons are the brain's source of acetylcholine.[29] There are direct projections to the thalamus from LDT/PPT with a known role in the generation of slow oscillations and sleep spindles,[30] which together represent a neurophysiologic sign that information transfer to the cortex is likely blocked.[31] As with the noradrenergic LC, activity of the LDT/PPT is high during waking consciousness and decreases during NREM sleep.[15] However, in contrast to the LC and other monoaminergic neurons, the cholinergic LDT/PPT is also active during REM sleep, during which the cortex is aroused. Furthermore, activation of cholinergic neurons in LDT or PPT induces REM sleep.[32] Thus, both states of cortical activation across the sleep-wake cycle are associated with high cholinergic tone. General anesthetics modulate cholinergic projections from the LDT/PPT. Sleep spindles occur during halothane anesthesia and are associated with decreased cholinergic transmission to the medial pontine reticular formation (PRF).[33,34] There is evidence that synaptic and extrasynaptic γ-aminobutyric acid (GABA) receptors play a role in modulating LDT neurons,[35] which could provide a direct link to molecular mechanisms of numerous general anesthetics. However, there has been relatively little study of the role of LDT/PPT in anesthetic mechanisms, with a greater focus on cholinergic neurons in the basal forebrain.

Pontine reticular formation. The PRF is part of the reticular activating system, which plays an important role in cortical arousal. Although GABA is the primary inhibitory neurotransmitter in the brain, the actions of GABA in the PRF are associated with cortical arousal.[36] For example, there is increased time spent in the waking state when the GABA_A receptor agonist muscimol is microinjected in the PRF.[37] When the GABA_A antagonist bicuculline is microinjected, wakefulness is suppressed, but REM sleep (another state of cortical arousal) is triggered. Vanini and colleagues found that *decreased* levels of GABA in the PRF correlated with isoflurane-induced unconsciousness, muscular hypotonia, and decreased respiratory rate.[38] Since the effects of anesthetics are normally associated with a *potentiation* of GABA activity, these findings highlight that a specific neuroanatomic and neurochemical milieu can play a unique and unexpected role in the mechanisms of consciousness and anesthesia. In addition, Vanini and colleagues found that GABA-ergic transmission in the rat PRF modulates the loss of consciousness induced by isoflurane but does not appear to affect emergence,[39] providing evidence for asymmetry between the two processes.

The mesopontine tegmental anesthesia area is located in the PRF. When pentobarbital is microinjected in this area, a reversible state with anesthetic traits is induced.[40] More recently, this phenomenon has been defined with greater spatial resolution, with the identification of around 1900 neurons in this area that can induce general anesthesia.[41]

Ventral tegmental area. Dopaminergic neurons of the ventral tegmental area (VTA) in the midbrain have not classically been considered key mediators of the sleep-wake cycle because of relatively less evidence of state-dependent changes compared with neurons in other brainstem nuclei. This view has been challenged in sleep neurobiology.[42] A dopaminergic pathway regulating sleep-wake states has been identified in *Drosophila*[43] and dopaminergic neurons of the VTA have more recently been found to play a role in mammalian sleep.[44] There has been renewed interest in the ability of dopaminergic activity to reverse or accelerate recovery from general anesthesia. Studies of the dopamine agonist methylphenidate have revealed an ability to reverse the sedative effects of both isoflurane and propofol.[45,46] VTA appears to be the source of the dopaminergic transmission mediating arousal during exposure to anesthesia, as evidenced by the fact that electrical stimulation of the VTA or selective stimulation of VTA dopaminergic neurons can reverse anesthetic-induced unconsciousness.[47,48]

Hypothalamus

Ventrolateral preoptic nucleus. The anterior hypothalamus has long been hypothesized to play a role in sleep-wake regulation.[49] VLPO is a structure in this region that transmits GABA and galanin.[50] Neurons in VLPO are maximally active during NREM and REM sleep;[51,52] the median preoptic nucleus (MnPO) is also active during sleep. Of note, the activity profile of GABA-ergic neurons in VLPO correlates with sleep amount, whereas the activity of GABA-ergic neurons in MnPO correlates with homeostatic sleep pressure or propensity.[53] Importantly, activity of the VLPO during sleep is correlated with inhibition of other arousal centers in the brainstem and hypothalamus.[51,54] Given its potentially central role as a mediator of sleep, VLPO became an attractive candidate as a mediator of anesthetic-induced unconsciousness. Nelson and colleagues demonstrated activation of VLPO after systemic administration of propofol or pentothal[55]; recent studies have examined the mechanistic significance of these findings. Eikermann and colleagues conducted studies of rats with *chronic* lesions of

VLPO, finding that ablation of VLPO resulted in sleep deprivation (as expected) but conferred *increased sensitivity* to the effects of isoflurane.[56] This finding would argue against a critical role of VLPO in the mechanism of anesthesia. However, Moore and colleagues demonstrated that *acute* lesions of VLPO conferred *resistance* to the effects of isoflurane, an effect that appeared to be mediated specifically through the sleep-active neurons in VLPO.[57] These neurons are actually depolarized (i.e., activated) by isoflurane. Taken together, these data suggest that VLPO plays a role in anesthetic-induced unconsciousness (as evidenced by acute lesion data), but that the effects of sleep deprivation associated with chronic VLPO lesions could overwhelm this role. Curiously, direct administration of dexmedetomidine, an α-2-adrenergic agonist, to the VLPO can destabilize the state of isoflurane anesthesia.[58]

Orexinergic neurons. Orexinergic neurons are found in the lateral hypothalamus and provide an important arousal stimulus for the cortex. There are two types of orexin (A and B), which are also referred to as hypocretins. Orexinergic neurons innervate other arousal centers in the brainstem and basal forebrain, and fire maximally in the waking state, are suppressed during NREM sleep, and show occasional bursts during phasic REM sleep.[59,60] Dysfunction of the orexinergic system is associated with narcolepsy in both human and animal models.[61,62] The often dramatic delay of anesthetic emergence in narcoleptic patients[63] has motivated the study of orexin in anesthetic mechanism. Orexins attenuate the effects of isoflurane,[64] propofol,[65] ketamine,[66] and barbiturates,[67] using various measures. Local infusion of orexin in the basal forebrain is associated with electroencephalographic (EEG) arousal and decreased emergence time in animals anesthetized with sevoflurane[68] and isoflurane.[69] Microinjection of propofol in the perifornical region of the hypothalamus (the locus of orexinergic neurons) is associated with a decrease in cortical acetylcholine, an important mediator of arousal.[70] Importantly, both genetic and pharmacologic studies have demonstrated that orexins play an important role in emergence from sevoflurane and isoflurane anesthesia, but not induction.[71] This seminal study suggested that there is a distinct neurobiology of induction and emergence, and formed the basis for a theory of "neural inertia" across state transitions.[72] Of note, halothane did not show an effect on orexinergic neurons and emergence time was not altered in orexin knockout mice.[73] These findings have been confirmed for propofol anesthesia: propofol reduces activity in orexinergic neurons in rats and infusion of orexin in the basal forebrain affects emergence time, but not induction time.[74] Orexins might facilitate emergence from anesthesia through actions in the basal forebrain.[75]

Tuberomammillary nucleus. The TMN is located in the caudal hypothalamus and is the brain's source of histamine, an arousal-promoting transmitter. TMN activity and histamine levels are highest during wakefulness and lowest during sleep;[76] the TMN is thought to have a relationship of reciprocal inhibition with the sleep-promoting GABAergic neurons of the VLPO.[51,54,77] Histamine release in the anterior hypothalamus is depressed during sleep[78] and halothane anesthesia.[79] Systemic administration of propofol, pentothal, and the GABA agonist muscimol all result in decreased activity in the TMN.[55] Microinjection of histamine in the nucleus basalis magnocellularis of the basal forebrain reverses the depressant effects of isoflurane on the EEG, an effect likely mediated by H1 histamine receptors.[80] A recent study in which $GABA_A$ receptors were genetically removed demonstrated that histaminergic neurons are resistant to the effects of propofol.[81] However, at the behavioral level, there was no effect of propofol on loss-of-righting reflex, a surrogate for anesthetic-induced unconsciousness. Thus the role of TMN and histaminergic transmission in the mechanism of anesthesia is still unclear.

ROLE OF THE THALAMUS

The thalamus is composed of more than 50 nuclei and subnuclei that can be grossly classified as relays for sensory input from the periphery or multimodal, integrative regions that receive input from the cortex. Additionally, the thalamus is critical for transmitting arousal signals from the brainstem and for regulating cortical communication. The involvement of the thalamus in arousal, sensory processing, and cortical computation is likely critical for normal consciousness. As such, the thalamus has been of continued interest to those investigating mechanisms of anesthetic-induced unconsciousness.

The thalamus has been proposed as an ON/OFF switch for anesthetic state transitions.[82] This theory was generated based on the consistent metabolic depression of the thalamus by a number of inhaled and intravenous anesthetics[83-85] (with the exception of ketamine),[86] suggesting that it could serve as an effective OFF switch. The hyperpolarization of the thalamus would shift tonic firing to burst firing that—as with sleep—would prevent afferent sensory stimuli from arousing the cortex. Importantly, however, sensory nuclei in the thalamus (and their connectivity to the cortex) appear to be less involved in anesthetic-induced unconsciousness compared to the higher-order or "nonspecific" nuclei.[87,88]

Evidence for the thalamus as an ON switch has been derived primarily from animal experiments, in which stimulation of the centromedial thalamus by either nicotine or antibodies blocking voltage-gated potassium channels could reverse the effects of inhaled anesthetics.[89,90] Although microinjection of large doses of nicotine into the thalamus could precipitate anesthetic emergence, antagonism of nicotinic acetylcholine receptors in the same location did not appear to contribute to anesthetic-induced unconsciousness. Central thalamic activation results in behavioral improvement in humans with traumatic brain injury.[91] A study in humans demonstrated that (spontaneous) activation of the thalamus along with other subcortical structures is correlated with recovery from anesthesia, suggesting the involvement of the thalamus in the primitive or "core" consciousness observed at emergence.[92]

Nonspecific nuclei of the thalamus have been proposed as a computational blackboard for the cortex.[93] Thus if the mechanism of anesthetic-induced unconsciousness was achieved primarily by a suppression of cortical computation, a depressed thalamus should be the result. To address this question, Velly and colleagues conducted a neurophysiologic study using scalp EEG (reflecting cortical signals) and subthalamic nuclei electrodes (argued to reflect thalamic activity).[94] Induction of anesthesia with either propofol or sevoflurane was associated with cortical rather than subcortical changes, suggesting that the depression of the thalamus identified through neuroimaging studies reflected an effect rather than a cause of anesthetic-induced unconsciousness. Other case studies in humans suggest concurrent suppression of thalamus and cortex during induction of propofol.[95] Furthermore, more precise neurophysiologic recordings of thalamus and cortex in animal models suggest that effects of propofol on central thalamic activity precede effects on the cortex; interestingly this was found during the spontaneous induction of sleep as well.[96] Other animal studies have found that attenuation of high-frequency oscillations by propofol is more pronounced in the thalamus than the cortex.[97]

The prior two possibilities (thalamic switch or computational blackboard for the cortex) treat the thalamus as a passive player in general anesthesia. However, more recent data suggest that it might, instead, play an active role. A computational study using human EEG data and modeling suggested that the action of propofol on GABA receptors in the nucleus reticularis generates a hypersynchronous alpha rhythm (8-13 Hz) with the frontal cortex that blocks sensory input.[98] Hypersynchrony of alpha may block the flexible corticocortical communication required for normal consciousness.[99] A recent animal study identified alpha synchronization between thalamus and medial prefrontal cortex during propofol induction.[100] The potential role of thalamocortical interactions in anesthetic-induced unconsciousness prompts further discussion of the thalamus and its connectivity to the cortex.

CORTICAL-SUBCORTICAL CONNECTIVITY

The closely integrated function of the cortex and thalamus suggests that the two can be treated as a single *thalamocortical system*. The thalamocortical system undergoes state-dependent changes across the sleep-wake cycle, and is thought to play a critical role in consciousness. This role is defined by its ability to integrate the activities of functionally diverse cognitive modules, a property that is critical for subjective experience.[101]

Recent studies using functional magnetic resonance imaging (fMRI) have refined the role of thalamocortical connectivity in anesthesia. One study identified a propofol-induced disruption of connectivity between the thalamus and lateral frontal-parietal networks.[102] Similarly, a study of the specific nuclei (linked to particular sensory modalities) and nonspecific nuclei (linked to integrative functions) found that disrupted connectivity between the nonspecific nuclei and the cortex best accounted for a reduction in the level of consciousness by propofol.[87] Recently, the inhaled anesthetic sevoflurane has been shown to functionally disconnect the thalamus and cortex, especially frontal cortex.[103,104] Notably, a consistent finding of neuroimaging studies is that the thalamocortical connectivity of primary sensory networks is relatively well preserved despite anesthetic-induced unconsciousness.

The finding of impaired thalamocortical connectivity in association with anesthetic-induced unconsciousness has not been universal. An fMRI study of propofol revealed more profound functional disconnections between the cortex and putamen, a subcortical structure in the basal ganglia.[105] In contrast, thalamic connectivity was relatively well preserved. The potential role of the striatum (composed of the putamen and caudate) in anesthetic-induced unconsciousness has been demonstrated in a study of rats undergoing isoflurane anesthesia.[106] This study was conducted with fMRI and found that the functional connection between the frontal cortex and the basal ganglia was disrupted during general anesthesia. A functional disconnection of association cortex and subcortical structures has also been shown by fMRI in a study of propofol-induced unconsciousness in humans.[107] With improved spatial resolution of 7T fMRI machines and templates for brainstem nuclei,[108] future studies can focus on identifying with greater precision the critical subcortical and cortical interactions or functional disconnections that contribute to anesthetic-induced unconsciousness.[109]

CORTICAL CONNECTIVITY AND DYNAMICS

The last three sections were organized according to a bottom-up approach to consciousness and anesthesia, starting with the brainstem, and then moving to the diencephalon and thalamocortical system. Sleep is clearly generated through such bottom-up mechanisms[14]; however, anesthetics may suppress the *level* of consciousness through bottom-up mechanisms and *content* of consciousness through top-down (i.e., cortical) mechanisms.[12]

Early studies using positron emission tomography (PET) demonstrated regional depression in cortical areas, including lateral and medial frontal-parietal networks.[110] Disruption of fMRI-based functional connectivity in frontal-parietal networks has been demonstrated during anesthetic-induced unconsciousness induced by drugs with distinct molecular mechanisms, including propofol,[102,111] sevoflurane,[103] and ketamine.[112] However, the cortex is amenable not only to fMRI but also neurophysiological techniques of assessing connectivity, enabling data on anesthetic-induced unconsciousness with improved temporal resolution. EEG can be used to measure functional connectivity (the statistical covariation of the activities of brain regions), and directional or effective connectivity (the presumed causal influence of one brain region on another).[113] Using such techniques applied to EEG (in some cases with concomitant fMRI), disruption of frontal-parietal connectivity and surrogates of information exchange in humans has been consistently observed after administration of a variety of anesthetics with diverse molecular targets.[104,114-117] It has been suggested that such disruption of frontal-parietal connectivity, with implications for impaired information transfer of relevance to consciousness, might be a common mediator and proximate cause of anesthetic-induced unconsciousness.[118]

The inhibition of frontal-parietal communication is likely representative of a more global disruption of cortical communication. A study using high-density EEG and transcranial magnetic stimulation revealed an inhibition of cortical-effective connectivity after midazolam-induced unconsciousness.[119] After administration of the benzodiazepine, local cortical activation could be observed at the site of magnetic stimulation, but robust evoked potentials

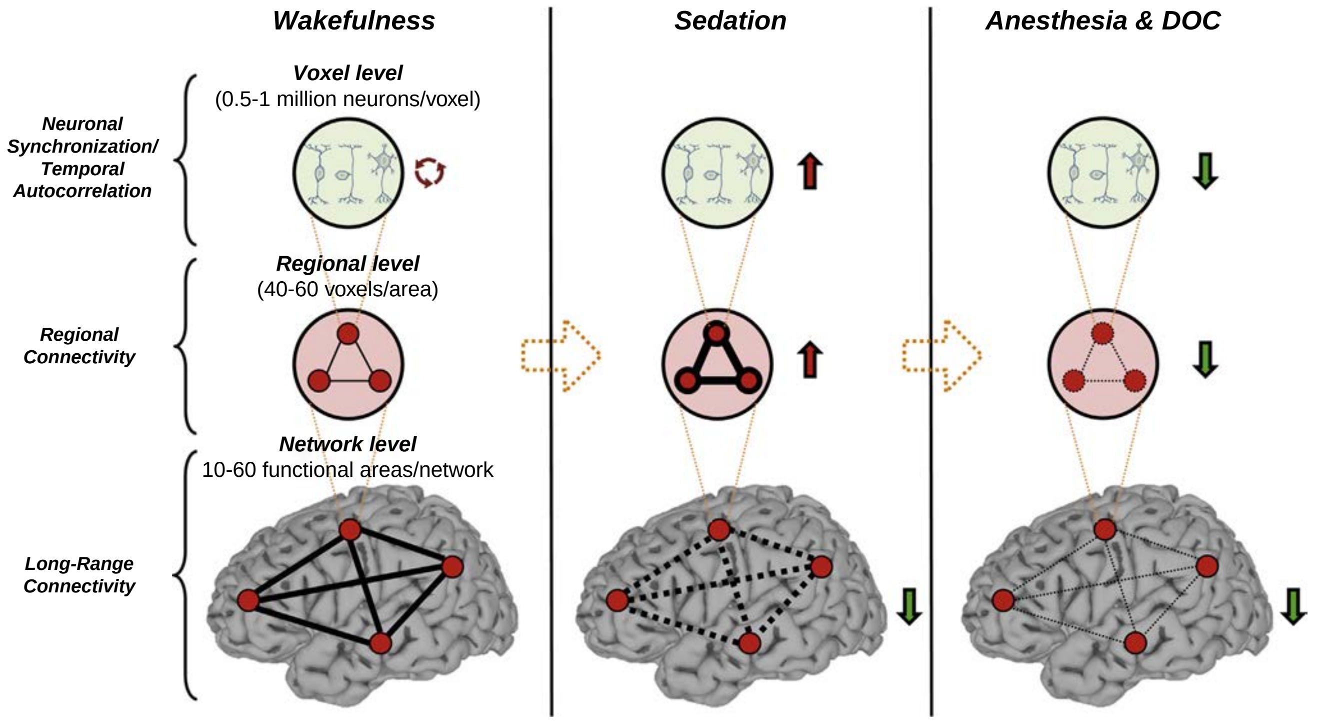

Fig. 9.3 Schematic summary of the consecutive stages of unconsciousness. Relative to the control state of wakefulness *(left column)*, sedation *(middle panel)* is marked by an increase of local/regional signal synchrony and consequent breakdown of global connectivity. Deep surgical anesthesia or disorders of consciousness *(DOC, right column)* is associated with collapse of both local/regional synchrony and global connectivity. (From Huang Z, Liu X, Mashour GA, Hudetz AG. Timescales of intrinsic BOLD signal dynamics and functional connectivity in pharmacologic and neuropathologic states of unconsciousness. *J Neurosci*. 2018;38[9]:2304–2317.)

were terminated at less than 100 milliseconds, and cortical communication was limited. Of note, this finding is consistent with findings in NREM sleep.[120] This perturbational approach determined that the complexity of cortical response to a stimulus decreased during sleep, general anesthesia, and disorders of consciousness.[121] The concordant findings across physiologic (sleep) and pharmacologic (anesthesia) states of unconsciousness may reflect a common neurophysiologic mechanism of disrupted cortical connectivity through slow oscillations, which share a number of characteristics in NREM sleep and general anesthesia.[122] A study of three epilepsy patients with intracranial neurophysiologic monitoring[123] revealed that, within 5 seconds of propofol-induced unconsciousness, there was a dramatic increase in the power of slow oscillations. Although single-unit neuronal activity was initially suppressed, it returned to baseline (or above baseline) but was fragmented into highly active and quiescent periods. Neural firing became coupled with the slow oscillation. However, the slow oscillations themselves demonstrated decay in phase coupling with increased distance across the cortex. Thus neuronal spike activity became fragmented into "on" and "off" periods, which became temporally uncoordinated across the cortex. These neurophysiologic conditions dramatically reduce the probability of meaningful corticocortical communication.

More recent trends of analyzing cortical changes during states of unconsciousness take a dynamic approach that reflects not just connectivity configurations but the repertoire of states that can be accessed during general anesthesia. For example, there is a contraction of dynamic repertoire and neural signal diversity during propofol-induced unconsciousness[124,125] that would preclude the kind of flexibility required for normal conscious experience. Dynamic patterns are impaired during general anesthesia and cortical dynamics are stabilized during general anesthesia.[126] This is likely a discrete, multistage process with distinct dynamic signatures during sedation and general anesthesia (Fig. 9.3).[127,128] Relating dynamics to connectivity, it appears that the repertoire of functional connectivity patterns in the primate brain becomes more tethered to structural/anatomical connectivity patterns during the anesthetized state.[129] Of note, animal studies suggest that the return of consciousness after general anesthesia is defined by discrete neural states that reconfigure during emergence.[130]

In the next section, we discuss memory, the thread that links conscious experiences together to form the narrative of "self."

Memory

HISTORY AND TERMINOLOGY

Modern understanding of the structure, function, and organization of human memory is deeply informed by the study of amnesia. The most renowned demonstration of this principle occurred in 1957, when Brenda Milner reported the remarkable case of Henry Gustav Molaison (1926–2008),[131] an amnesiac who would become known famously as H.M., and who would represent the single most influential case study in the history of neuroscience. In a procedure intended to treat a refractory seizure disorder, significant portions of the medial temporal lobe (MTL) were removed bilaterally—including the hippocampus, amygdala, and adjacent parahippocampal gyrus. H.M. developed profound and enduring anterograde amnesia, and was unable to establish any new conscious memory, irrespective of the sensory modality. He also developed a temporally graded window of retrograde amnesia, with impaired recall of events occurring during the 3 years preceding his surgery. However, most of his associated cognitive functions—perceptual processing, language, attention, access to semantic knowledge, and capacity to retain small packages of information in constant rehearsal—remained largely or entirely intact. Prior to this report, the prevailing theory—articulated by Canadian neuropsychologist Donald Hebb[132]—was that there was no brain region dedicated to memory function. Instead, memory processes were thought to be distributed and integrated into region-specific perceptual and cognitive functions. For example, the visual attribute of a memory would be wholly served within the striate and extrastriate cortical regions responsible for visual perception. The description of H.M. immediately disproved this model. It became clear that the MTL was a specialized and obligatory structure for the establishment and early maintenance of *all* conscious memory, irrespective of the modality. The trajectory of memory research was profoundly transformed. Initially, largely independent branches evolved to focus on the structural-functional organization of the MTL (Fig. 9.4*A*) and the nature of cellular-level neuroplastic processes—the latter notably marked by the description of long-term potentiation (LTP) by Timothy Bliss and Terje Lømo in 1973.[133] Subsequently, emerging technologies enabled the development and investigation of systems-level constructs. Examples include the use of EEG and magnetoencephalography to assess the role of oscillatory phase synchronization in neuronal assemblies,[134] fMRI to identify large-scale networks associated with specific memory functions,[135] and machine learning to classify complex neural network patterns predictive of memory.[136]

Amnesia is the term used to describe one of the cardinal properties of general anesthesia. As understood by most anesthesiologists and laypeople, this description is phenomenological; it states that patients do not recall the events that occur to them while receiving anesthesia. However, this usage confuses a critical mechanistic and semantic distinction. Patients in the deepest states of anesthesia are unable to process and bind perceptual elements into an integrated conscious experience. From the perspective of cognitive neuroscience, the "amnesia" of general anesthesia is not a primary failure of memory, but rather a failure of consciousness. It simply reflects that a conscious experience cannot be reconstructed by memory processes when it does not exist in the first place. Further confusion is added by the frequent use of the term *awareness*—a synonym for conscious perception—to describe the case in which a patient consciously recalls events occurring during the administration of an anesthetic. This ignores the fundamental principle that memory is functionally dissociable from consciousness. Awareness is *necessary* for the establishment of memory under anesthesia, but it is not *sufficient*. Conscious recall can occur only if awareness is accompanied by memory processes in the MTL and elsewhere that establish and preserve a representation that can be reconstructed later.

These important distinctions establish the axiom that patients who form memories while under anesthesia cannot have been truly unconscious; they must have possessed some conscious substrate from which the memory derives. However, the converse inference is not always true: the existence of consciousness will not necessarily lead to the existence of memory if an anesthetic drug is present. Evidence to support this statement is unambiguously encountered in everyday anesthetic practice—patients receiving a small dose of propofol or midazolam who engage in a cogent conversation that they are later unable to recall, or in patients emerging from general anesthesia who follow commands to demonstrate that extubation can proceed safely, yet later cannot recall anything related to this clearly conscious event. Anesthetic drugs must therefore have direct effects on memory processes that are dissociable from those on consciousness—and it is this observation that provides a framework for the systematic study of how anesthetic drugs affect memory.

Organization and Function of Normal Memory

MULTIPLE MEMORY SYSTEMS

When the term *memory* is used in everyday language, it almost always refers to declarative memory. Declarative memory is the representation of prior events and knowledge that is accessible to consciousness and can be manipulated by attention and executive function. It is the form of memory referred to in the context of anesthetic amnesia.

Further important organizational structure exists within declarative memory. The first is the distinction between episodic and semantic memory. *Episodic memory* is the recollection of events with a clear spatiotemporal context (as when recalling autobiographical events with a distinct sense of personal experience, time, and place), whereas *semantic memory* is the capacity to recall and apply meaning, facts, and knowledge without spatiotemporal context (as when recalling that Mount Everest is the tallest mountain in the world without any sense of time and place for the acquisition of that knowledge). The episodic memory system is fast-mapping and highly dependent on the MTL as well as frontal and parietal structures,[137,138] whereas the semantic memory system is slower and involves distributed cortical regions that closely map to the default mode network, a large-scale system that is active during the resting state and flow of spontaneous cognition.[135,139] The second organizational structure within episodic memory is the distinction between recollection and familiarity. *Recollection* involves remembering specific qualitative contextual details about a prior event, whereas in a *familiarity* judgment, there is a sense that an item has been encountered previously, but beyond that there are no added contextual details. The accepted understanding is that recollection and familiarity arise from distinct processes and neural architecture within the MTL. The perirhinal cortex receives input from sensory association areas and supports familiarity judgments through encoding and retrieval of the identifying qualities of an item (the "what" information). The parahippocampal cortex and entorhinal areas receive input from areas

processing spatial information (the "where" information), and support recollection through encoding and retrieval of context. The hippocampus links these two, binding item and context information, and appears necessary for recollection, but plays little or no role in familiarity.[140,141]

Other forms of memory are dissociable from declarative memory. Findings that amnesiacs could learn a hand-eye coordination skill even while possessing no memory of the task led to the distinction between declarative and *procedural* memory, which is dependent on the caudate nucleus.

Subsequently, memory-impaired patients were also found to have intact *priming*,[142] which is a nonconscious process in which exposure to a stimulus influences the response to a later stimulus—for example, amnesiacs can name pictures 100 milliseconds faster if they have seen them previously, despite having no declarative memory of the exposure.[143] The neural bases for priming effects are thought to arise within regions serving perceptual and contextual processing of the stimulus, and so vary with the nature of the task.[144] Lastly, a large body of work has extensively elucidated the *emotional memory* system. The classic experimental model is Pavlovian fear conditioning and its variants, wherein an emotionally neutral conditioned stimulus is paired with an aversive unconditioned stimulus, leading to an involuntary associative physiologic and/or behavioral response to the conditioned stimulus. The circuitry involves convergence of afferent information from all sensory modalities on the lateral nucleus of the amygdala, and the basolateral and central nuclei projecting widely to modulate processes in cortical and subcortical regions (see Fig. 9. 4*B*).[145,146] With the progressive description of these and other functional distinctions, the framework for understanding memory eventually shifted to models that contained multiple memory systems in the brain, distributed functionally and anatomically.[147]

Working memory refers to the capacity to maintain limited amounts of information in the stream of consciousness, which can be manipulated to perform complex cognitive tasks such as reasoning, comprehension, and learning.[148] The concept evolved from, and has largely replaced, earlier ideas about *short-term memory*, but the terms should not be used interchangeably, as working memory implies both a short-term memory store *and* the capacity for manipulation. The most influential current model, first proposed by Baddeley and Hitch in 1974,[149] divides working memory into capacity-limited component subsystems: a *phonological loop* that maintains information through vocal or subvocal rehearsal, such as when one holds a telephone number in mind; a *visuospatial sketchpad*, which holds and manipulates spatial, visual, and kinesthetic information; and a *central executive*, which is responsible for regulating selective attention and inhibition. A fourth subsystem, the *episodic buffer*, was later added to the model[150] and is responsible for the temporary storage of multidimensional representations and integration with declarative memory.

Working memory has long been understood to not involve the MTL,[151] although the belief that it has no role has recently been questioned in studies of spatial working memory.[152] Notwithstanding, current understanding of working memory suggests that it is served by persistent activity and flexible resource allocation in a distributed cortical network, with a critical hub in the dorsolateral prefrontal cortex (DLPFC) interconnected with parietal cortex, thalamus, caudate, and globus pallidus.[153] The functional and structural distinction between working memory and the MTL does not mean that working memory and declarative memory systems do not interact. Working memory depends on declarative memory representations to provide semantic meaning and context. During working memory tasks, cortical perceptual areas associated with representations of declarative memory become activated and show increased synchrony with prefrontal regions.[154] Reciprocally, encoding of declarative memory is strongly influenced by the nature of processing occurring in working memory, with deeper levels of executive processing resulting in better learning.[155]

The transition of memory from short-term stores through to stable long-term stores is experienced as continuous and was assumed to reflect sequential transfer across systems. However, this model is challenged by rare case examples of patients who have a selective short-term memory deficit but intact declarative memory function, and recent studies have reinforced the view that memories are formed in multiple systems in parallel.[156]

LONG-TERM POTENTIATION, SYNAPTIC TAGGING, AND THE CONSOLIDATION MODEL OF MEMORY

The consolidation hypothesis of memory was first proposed by Müller and Pilzecker in 1900.[157] They noted that memory for new information could be disrupted by learning other information shortly after the initial training. This effect, called *retroactive interference*, is temporally graded such that the susceptibility of the memory is greatest immediately after learning and decreases with time. Müller and Pilzecker proposed that the memory trace must initially exist in a fragile state, but subsequently becomes stable through the process of *consolidation.* The consolidation hypothesis remains the framework for understanding the temporal course of memory processes and behavior.

For a memory trace to be consolidated, it must of course be created. The term used to describe this process is *encoding.* Encoding implies that the networks mediating the neural representation of an event as it is experienced do not immediately return to their previous state and are modified in such a way that potentiates reactivation of that representation. The *synaptic plasticity and memory hypothesis* states that activity-induced synaptic plasticity is both necessary and sufficient for the information storage underlying memory,[158] and within this framework encoding implies that some form of synaptic plasticity has been initiated. However, encoding cannot in itself assure the propagation of a memory trace. Encoding creates the potential for the formation of a long-term memory.

The minimal events that constitute the neural correlates of encoding are incompletely understood. Cellular models demonstrate that functional changes in synaptic strength can occur in the absence of any structural change in dendritic spines.[159] The perpetuation of these initial changes through structural and functional remodeling represents the neural correlate of memory consolidation. The prevailing cellular model for this is LTP,[160] which describes a durable increase in synaptic transmission efficiency following a stimulation protocol. It is now recognized that LTP occurs richly throughout the hippocampus, as well as in other afferent pathways.[161] LTP can be induced by nonphysiologic high-frequency stimulation, but also by stimulation protocols that resemble physiologic activity, the most important being bursts in the theta range (4-8 Hz).[162] This is of notable relevance to memory, as synchronized hippocampal theta oscillations appear critical to successful memory behaviors.[134]

The breadth and depth of literature on the mechanisms of LTP are far too voluminous to summarize here. Nonetheless, certain principles are essential and relevant to anesthesia studies and can be stated succinctly. The induction of most forms of LTP requires activation of postsynaptic *N*-methyl-D-aspartate (NMDA) receptors,[163] followed by influx of Na^+ and Ca^{2+}. This rise in intracellular Ca^{2+} is the critical trigger for LTP. Calcium-calmodulin-dependent kinase II (CaMKII) is then activated and autophosphorylated,[164,165] leading to cytoskeletal reconfiguration.[166] Activation of several other cell-signaling cascades also contribute to LTP. The terminal expression of LTP is protein synthesis, occurring in both the soma and local dendrites, and resulting in enduring structural changes at the synapse.[167] Protein synthesis inhibitors have been demonstrated to consistently prevent sustained LTP in vitro and learning in vivo.[168]

LTP thus proceeds in two phases: early LTP (E-LTP) is independent of protein synthesis and can be sustained across an interval of minutes to a short number of hours, while late LTP (L-LTP) is dependent on intracellular signaling and protein synthesis and can be sustained across many days. The *synaptic tagging and capture hypothesis* provides a mechanistic explanation for the observation that the persistence of synaptic potentiation (and memory) is influenced by events surrounding encoding.[169] In this model, synapses activated during E-LTP become tagged via a protein synthesis-independent mechanism. This tag establishes the potential for sustained L-LTP, but for the cascade to continue the tags must capture plasticity-related proteins (PRPs) synthesized in the soma or dendrites in response to neural activity. The synaptic tagging model explains how the thousands of dendrites of a single neuron can be engaged in memory stabilization processes in various states of evolution, because the tagging and PRP capture need not occur as a singular event.

RECONSOLIDATION

A major shift the in understanding of consolidation occurred in 2000, when Nader et al. reported that an old memory for auditory fear conditioning, which would normally not be sensitive to protein inhibitors, can be made newly sensitive if it is retrieved.[170] The implication is that retrieval of a memory renders it transiently plastic, after which it restabilizes. This process is termed *reconsolidation*, and the period of plasticity is termed the *reconsolidation window*. The mechanism shares many of the LTP processes that are associated with initial consolidation, but also has features that are quite distinct at both the cellular and systems level.[171] Reconsolidation serves as a modulatory process that enables the strengthening of an existing memory, but it is also clear that it provides a window within which an existing memory is malleable and can be updated with the addition of novel information, or diminished through interruption of restabilization processes.[172] These latter properties have generated significant translational interest because of repeated demonstrations of the ability to modify or even eliminate fear memory in animals through pharmacologic and behavioral interventions that interrupt reconsolidation.[173] Indeed, the erasure of fear memory in humans can be demonstrated through performance of a behavioral extinction procedure during the reconsolidation window.[174]

PHASE SYNCHRONIZATION AND COUPLING

The neurons in assemblies and networks undergo oscillatory activation and inhibition. Phase synchronization of these oscillations supports neural communication by creating transient and dynamic associations between different functional brain regions. Phase synchronization appears to be fundamental to neural plasticity and memory,[134] and numerous studies have demonstrated that dynamics of synchrony during memory tasks can be related to both long-term[175] and working memory[176] performance. Gamma-band (30-100 Hz) synchrony is believed to support an important form of Hebbian plasticity, termed spike-timing-dependent plasticity, in the hippocampus. Both computational models and experimental data provide evidence that rapid changes in the frequency and phase of gamma rhythms modulate this form of plasticity through coordination of presynaptic spikes in assemblies of neurons, effectively classifying which assemblies are interpreted as a single event.[177]

Another property of relevance to memory coding is the coupling of gamma oscillations to the phase of slower, synchronized oscillations within the theta-band (4-8 Hz).[178] Theta oscillations, which are prominent in the hippocampus and entorhinal cortex, undergo phase resetting in response to a stimulus. The phase reset involves widely distributed regions, and is thought to serve as an efficient mechanism for the optimization of interregional communication.[179] Theta phase resetting and synchrony in the hippocampal-entorhinal system are implicated in declarative memory,[180] and in the amygdala-hippocampal system in fear-based memory.[181] Coupling between theta phase and gamma amplitude is connected to declarative memory formation,[180,182] and, in an elegant model, is proposed to form a code for representing multiple items and spatial representations in an ordered way.[183] Coupling between theta phase and gamma phase enables a more precise temporal coordination of neuronal spikes, and may code for separated representations of multiple items in working memory.[184]

Effects of Anesthetic Drugs on Declarative Memory Function in Humans

There are multiple potential pathways by which anesthetic drugs could interfere with memory and cause amnesia. Most of these cannot be directly assessed in humans, but the plausibility of candidate mechanisms can be indirectly examined by designing experiments that are informed by the characteristics of known memory processes. Studies of anesthetic effects on memory are most informative when conceptualized and designed with reference to robust methods and findings taken from the larger body of memory research.

BEHAVIORAL STUDIES OF RETROGRADE MEMORY EFFECTS

Notwithstanding some isolated case reports, systematic investigations have found no evidence that anesthetic drugs cause retrograde amnesia in humans. There is no retrograde amnesia associated with induction doses of thiopental,[185] methohexital,[185] or propofol.[186] Adult patients have normal memory for visual stimuli presented 4 minutes before administration of midazolam at doses of 2, 5, and 10 mg.[187] Similarly, memory is normal for word lists learned in the preoperative holding area or operating room immediately before induction.[188] Studies in pediatric patients have shown normal memory for pictures presented immediately before sedation with midazolam,[189] propofol,[190] and dexmedetomidine.[191] In controlled laboratory settings using human volunteers and target-controlled infusions, studies have found no impairment of memory for pictures[192] or words[193,194] presented before sedative infusions of propofol, midazolam, thiopental, or dexmedetomidine.

There is some evidence from controlled studies that anesthetic drugs may instead lead to the opposite effect, in which memory for material presented prior to drug administration is enhanced—a phenomenon termed *retrograde facilitation*. In one study using a mildly sedative dose of propofol,[195] memory for words learned immediately prior to drug administration was enhanced throughout the testing period of 24 hours. Similar effects are described for midazolam and other benzodiazepines in the psychopharmacology literature.[196] The mechanistic explanation for retrograde facilitation can be framed by an understanding of *retrograde interference*—the observation that mental exertion inhibits the consolidation of recently formed memories, with the newest memories being most vulnerable.[197] The induction of new LTP interferes with recently formed LTP and memory performance, even when the tasks are unrelated.[198] However, when the induction of new LTP is blocked by administration of a selective NMDA antagonist after learning, interference with recently formed LTP does not occur, and memory performance improves.[199,200] A parsimonious explanation for the retrograde facilitation seen with propofol and benzodiazepines is that they similarly modulate the induction of new LTP via a GABA-ergic pathway, freeing consolidation resources that enhance survival of recently formed memory.

The findings of retrograde facilitation and absence of retrograde amnesia are suggestive that the key mechanisms of GABA-ergic anesthetic amnesia, at least in humans, involve very early processes in the consolidation cascade. It is more difficult to rationalize that downstream sequences represent principal targets. Were this the case, the expected effect would be interference with ongoing consolidation of memory for events occurring in the past, creating a window of retrograde amnesia. Nonetheless, an alternate model to the induction hypothesis suggests that GABA-ergic anesthetics exert a direct effect on downstream protein transcription processes,[201] based on evidence from rodent studies.[202]

The absence of pharmacologic retrograde amnesia does not dismiss the repeated finding that, in the clinical setting, a percentage of patients will not recall the immediate preanesthetic period—an effect that increases with age.[203] Although not systematically studied, the complex noradrenergic-mediated effects of acute stress and anxiety on memory may be contributory.[204]

MATHEMATICAL MODELING OF ANESTHETIC AMNESIA

Mathematical modeling of memory decay has been used to characterize the amnestic effects of multiple intravenous anesthetic drugs,[193] which are accurately described by a two-parameter power decay function:

$$m_t = \lambda t^{-\Psi}$$

where λ reflects the initial memory strength (an index of encoding), and ψ expresses the rate of decay (an index of consolidation). The drugs are characterized by marked differences in the way they modulate the two coefficients. Propofol is an archetypal amnestic drug—it permits robust encoding of material, but the information undergoes accelerated decay because of a failure of consolidation. In contrast, dexmedetomidine archetypally causes memory impairment because of a failure of information to be strongly encoded but has little or no effect on the subsequent consolidation of memories that are encoded. The benzodiazepine midazolam behaves like propofol at lower doses—selectively causing consolidation failure while leaving encoding intact—but with increasing dose a significant encoding impairment emerges. Thiopental in contrast causes marked encoding failure but demonstrates minimal effect on consolidation. The discrepant patterns observed imply that nonspecific $GABA_A$ agonism is not per se sufficient to explain the ability of a drug to cause consolidation failure.

ANESTHETIC EFFECTS ON ATTENTION AND AROUSAL AS MODULATORS OF ENCODING

The effect of anesthetic drugs on encoding processes is related to the modulation of attention. Selective attention is governed by distinct networks mediating alertness, target orientation, and executive control[205]; involves modulation of neuronal phase synchrony across short- and long-range connections[206]; and is necessary for the successful establishment of declarative memory.[207] The dominant effect of most anesthetic drugs on attention is decreased arousal, with the notable exception being the NMDA antagonist ketamine, which has dominant effects on orienting and selection.[208] Thiopental mimics the effect of an attentional challenge task in decreasing activation in the left inferior prefrontal cortex (LIPFC), an effect that is not seen with propofol.[209] When tested at 225 minutes, arousal is predictive of memory for thiopental and dexmedetomidine, while propofol causes a significantly greater loss of memory than would be predicted by modulation of arousal alone.[194] In mathematical modeling of anesthetic amnesia,[193] arousal predicts the coefficient of encoding strength with precision for a range of sedative concentrations of dexmedetomidine, thiopental, midazolam, and propofol. In sum, arousal is predictive of subsequent memory for drugs that impair memory dominantly through causing encoding failure.

NEUROIMAGING STUDIES OF CORTICAL ENCODING PROCESSES

A limited number of functional neuroimaging studies have evaluated the effect of anesthetics on cortical regional activation during memory encoding. An early PET study investigating sedative doses of propofol using a word memory task[210] identified that activation in LIPFC—a region associated with encoding and subsequent memory for language tasks—was conserved, suggesting that propofol did not block the processes required to support successful encoding. In contrast, activation in DLPFC—a region most associated with executive control functions and cognitive control of motor planning[211]—was decreased. In a subsequent investigation using an auditory depth of processing task, activation of LIPFC was found to be decreased by sedative doses of thiopental, but again was relatively unaffected by propofol.[209] However, other studies have identified decreased activation in encoding areas. An fMRI study of sentence comprehension during light sedation with propofol found that decreased memory for sentences was related to decreased activation in the left inferior frontal gyrus (LIFG, within the LIPFC) and the middle temporal gyrus.[212] Another study using a single-word encoding task showed decreased activation in LIFG at levels of propofol sedation causing memory loss, but also found intact connectivity between LIFG and a number of frontoparietal and temporal regions associated with verbal processing and memory tasks, including the middle temporal gyrus and precuneus.[213]

Some functional neuroimaging studies have used experimental tasks similar to memory encoding tasks while evaluating sedative doses of anesthetic drugs, but have not assessed memory encoding as a primary aim; these are informative, but must be interpreted with caution. An early PET study of sedative doses of midazolam using a tone detection paradigm reported a dose-dependent activation decrease in Brodmann areas 9, 10, and 46, which overlap regions of both DLPFC and LIPFC.[214] An fMRI study of semantic word processing during propofol sedation found a dose-dependent decrease in activation of the LIFG, despite intact behavioral responses.[215] An fMRI study of low-dose dexmedetomidine reported a generalized suppression of bilateral prefrontal activation in Brodmann areas 9 and 10 during an emotional picture memory task, but encoding performance was not specifically analyzed.[216] A recent study using music stimuli found decreased activation in primary and secondary auditory processing areas at sedative doses of dexmedetomidine and midazolam, but not with propofol.[217] Other neuroimaging studies evaluating resting state networks, or passive activation in response to stimuli at nonresponsive levels of sedation, should not be viewed as memory experiments.

Neuroimaging Studies of Medial Temporal Lobe Function

Two methodologically similar studies used event-related fMRI to evaluate MTL activation during low-dose infusions of propofol and dexmedetomidine. The degree of amnesia caused by propofol can be linearly related to decreased activation in the hippocampus bilaterally,[218] an effect that behaviorally corresponded to a failure of consolidation processes. In contrast, dexmedetomidine does not reduce the overall level of hippocampal activity, but the subsequent-memory effect is attenuated, and dynamics of hippocampal activation are less predictive of subsequent memory[216]; one interpretation is that this reflects a downstream effect from weakened cortical encoding processes. An earlier study of the benzodiazepine lorazepam and the cholinergic antagonist scopolamine found decreased memory to be correlated with decreased activation in the anterior hippocampus,[219] accompanied by decreased activation in the encoding-related regions in the fusiform gyrus and inferior frontal cortex. In a largely exploratory investigation, 0.25% sevoflurane was found to reduce hippocampal activation in response to auditory and visual stimuli, but no memory performance was assessed.[220]

A few studies have evaluated anesthetic effects using electrocorticography and depth electrodes implanted in epileptic patients, but none have been dedicated to memory function. One notable study evaluated the effects of mildly sedative concentrations of propofol on hippocampal spectral coherence and power characteristics at rest.[221] The main finding was a significant increase in hippocampal-rhinal spontaneous coherence in the delta-band, but minimal changes in other bands; cortico-hippocampal coherence was not assessed.

STUDIES OF CORTICAL EVENT-RELATED POTENTIALS

A number of memory-dedicated studies have used the event-related potential (ERP)—a small but stereotypic positive and negative signal fluctuation in the EEG time-locked to a stimulus, and which can be isolated through summation over multiple (usually at least 50) identical trials. ERPs are thought to emerge not because new oscillations are induced, but because of a stimulus-induced phase resetting of ongoing oscillations.[222]

An early ERP study[223] of scopolamine, lorazepam, and diphenhydramine suggested that drug-induced effects on arousal and memory may be electrophysiologically dissociable, although memory was not assessed directly. Changes in the P1N1 and N1P2 early complexes, associated with arousal, were seen for all three drugs. However, changes in later complexes associated with memory, notably the P3 and N2P3, were seen only with scopolamine and lorazepam, and not with diphenhydramine, an antihistamine that causes sedation but not amnesia. This work is extended by a series of studies evaluating intravenous anesthetics and using memory-specific experimental paradigms. In a verbal memory task, propofol amnesia was associated with decreased P300 amplitude at the time of the encoding task.[224] In a subsequent study in which multiple drugs were carefully dosed to equivalent levels of sedation,[225] the true amnestic drugs with memory effects independent of sedation—propofol and midazolam—caused decreased amplitude in the P300 and N2P3 components, with the latter being the best predictor of subsequent memory performance. Across all drugs studied, the N2 latency was related to reaction time, a surrogate measure of sedation.

Another study examined early- and mid-latency ERPs originating from the midline parietal precuneal region (Pz), and related them to coefficients describing the extent of encoding and consolidation failure.[226] Across drugs from multiple classes and at multiple doses, consolidation failure was closely correlated with the P2 amplitude and N2 latency observed at the time of encoding. As the visual P2N2 complex is known to originate from synchronous theta oscillations,[227] one possibility is that a common mechanism underlying the effect of anesthetic drugs on consolidation involves changes in theta oscillations across a distributed cortico-hippocampal network occurring at the time of consolidation induction. Further, the P2N2 and memory decay coefficient were also closely correlated with reaction time, which can be related to interregional synchrony.[228] Unfortunately, no direct measures of cortico-hippocampal theta synchrony have yet been performed in studies of pharmacologic amnesia. Another analysis[229] examined the *old-new effect*, a robust phenomenon in the parietal ERP that distinguishes the response to initial item exposure from subsequent exposures as a marker of memory strength. Propofol and midazolam caused a significant decrease in the old-new effect at 27 seconds, even though memory performance was maintained, demonstrating again an early marker of impaired memory processes that precedes behavioral detection.

Studies using very different experimental paradigms have evaluated auditory ERPs at multiple concentrations of propofol.[230,231] Propofol causes a dose-dependent decrease in mismatch negativity and early right anterior negativity, which are elicited in response to specific music signatures and are known to relate to associative memory operations. In contrast, the P1 complex, which derives from primary auditory processing, is not affected even at deep levels of sedation.

Nonhuman Studies of Anesthetic Effects on Memory Processes and Behavior in the Medial Temporal Lobe

ANESTHETIC EFFECTS ON MEDIAL TEMPORAL LOBE PLASTICITY

GABA-ergic interneurons project within and across subregions of the hippocampus,[232] providing an abundant density of possible targets for anesthetic drugs. In an early study using tetanic stimulation of the Schaffer collateral-commissural pathway,[233] isoflurane blocked the induction of LTP, and long-term depression (LTD) by low-frequency stimulation. These effects were reversed by the addition of the $GABA_A$ receptor antagonist picrotoxin, providing strong evidence that the effect of isoflurane on LTP is GABA-ergically mediated. In a similar protocol, amnestic concentrations of sevoflurane caused a failure of LTP which was prevented by the addition of the $GABA_A$ antagonist bicuculline.[234] A recent study of sevoflurane exposure in neonatal rats found reduced spine density of apical dendrites, synaptic ultrastructure damage, elevated expression of synaptic vesicle-associated proteins, and inhibition of LTP but not LTD.[235] One study of isoflurane, in which the hippocampus was studied 24 hours following anesthetic exposure, somewhat unexpectedly found improvement in cognitive performance, accompanied by evidence of upregulation of the 2B subunit of the NMDA receptor and enhanced LTP.[236]

A series of investigations have demonstrated that propofol inhibits the induction, but not the maintenance, of LTP, and has no effect on LTD. The effect is blocked by the addition of picrotoxin, implicating a $GABA_A$ receptor-mediated mechanism.[237,238] Notably, one study found that propofol inhibited LTP only at anesthetic, and not at amnestic concentrations.[238] Propofol has also been demonstrated to inhibit a number of component subprocesses of LTP.[239-241] Propofol reduces expression of activity-related cytoskeleton-associated protein (Arc) in the hippocampus in response to inhibitory avoidance training but does not appear to reduce Arc mRNA,[202] which is notable because it suggests a post-transcriptional mechanism.

The hippocampal $GABA_A$ergic interneuron population is notable for a high density of the α_5-subunit subtype. Of known significance to memory function, the α_5-$GABA_A$ receptor regulates the induction of LTP in response to a narrow range of frequencies in the theta range.[242] These observations have driven a series of anesthesia studies using α_5-$GABA_A$-knockout mice. Etomidate blocks LTP measured in CA1 neurons in wild-type mice, but not in α_5 –/– mutants, and behaviorally the α_5 –/– mutants are resistant to the amnestic effects of etomidate, but not to its general anesthetic effects.[243] Further, the effects of etomidate on LTP and memory behaviors are reversed by the addition of L-655,708, which selectively reduces the activity of α_5-$GABA_A$ receptors.[244] The behavioral findings were later replicated with exposure to 1 MAC of isoflurane, with memory deficits observed in wild-type mice, but not in α_5 –/– mutants or in wild types receiving L-655,708.[245,246] The increase in α_5-$GABA_A$ receptors caused by etomidate and isoflurane does not return to baseline for at least 1 week.[247]

The α_5-subunit subtype is not exclusive in its association with amnesia. α_4-$GABA_A$ receptors are concentrated in the dentate gyrus and dorsal thalamus, and α_4 knockouts are resistant to the amnestic effects of isoflurane but not to its general anesthetic effects.[248] More equivocally, β_3-$GABA_A$ receptor knockout mice have been reported to be resistant to the amnestic effects of isoflurane,[249] while in a study using β_3-$GABA_A$ receptor knock-in mutants, the β_3 subtype was not significantly associated with amnesia.[250] Similar equivocacy has been found in studies of the α_1 subtype.[251,252]

The effects of anesthetics on hippocampal theta oscillations in vivo have been studied. One study used a fear-conditioning paradigm to examine amnestic concentration of isoflurane, nitrous oxide, and halothane, and reported that suppression of hippocampal-dependent contextual conditioning was proportionate to slowing of theta peak frequency.[253] Another study also demonstrated that isoflurane caused slowing of theta oscillations in the CA1 neuronal bundle without changing absolute power,[254] while in contrast the nonimmobilizer F6, which causes amnesia without sedation or a loss of motor activity, caused a loss of theta oscillatory power without slowing. Scopolamine causes amnesia at doses associated with acceleration of theta oscillations, which might otherwise be expected to improve learning.[255] However, a significant loss of absolute power is also observed. Together these findings suggest that individual anesthetics may cause amnesia through distinct forms of hippocampal theta disruption.

Human and Nonhuman Studies of Anesthetic Effects on Fear Memory Systems

THE AMYGDALA-DEPENDENT FEAR SYSTEM

The amygdala is a cluster of interconnected nuclei sitting immediately anterior to the hippocampus, with afferent and efferent projections to a wide distribution of cortical and subcortical structures. It is critical to fear learning and memory, and the systematic study of amygdala-dependent classical (Pavlovian) fear conditioning has produced much information regarding the mechanisms and circuitry.[145,146] The basolateral nucleus of the amygdala (BLA) also modulates the encoding and consolidation of memory in the hippocampus and elsewhere in response to emotion, arousal, and stress.[256] The mechanism is dependent on noradrenergic projections terminating on both α and β receptors within the BLA,[257] and can be triggered by systemic stress mediators—notably glucocorticoids[258] and epinephrine.[259] Amygdalo-hippocampal connectivity occurs via direct and indirect projections, and is dependent on theta oscillatory synchrony.[181,260] The amygdala contains a number of rational targets for GABA-ergic anesthetic drugs.

STUDIES OF ANESTHETIC EFFECTS ON FEAR SYSTEMS IN NONHUMANS

As various forms of fear conditioning represent the dominant experimental method for studying memory in animal models, almost all studies of anesthetic effects on memory offer some insight into their effects on fear systems. Beyond the central conclusion from this sizeable body of literature that GABA-ergic anesthetics in general impair the acquisition of fear memory, a subset of studies are notable for their specific focus on fear circuitry and behavior.

There is substantial evidence that anesthetic effects on fear memory are mediated by GABA-ergic mechanisms in the amygdala. Selective injection of the BLA with midazolam blocks acquisition and stress enhancement of fear memory,[261] while lesions of the BLA block anterograde amnesia for an inhibitory avoidance task in rats receiving diazepam,[262] propofol,[263] and sevoflurane.[264] Further, injection of the BLA with the selective $GABA_A$ antagonist bicuculline blocks the effect of propofol[202] and midazolam.[265]

There are certain conditions under which anesthetic drugs can enhance fear memory. When propofol or ketamine is given immediately following conditioning, retention is enhanced,[266,267] which may represent a form of retrograde facilitation as described earlier, but retention is reduced when dexmedetomidine is similarly administered. In a rat model of PTSD, propofol and ketamine administered immediately after fear learning enhances long-term fear behavior, while dexmedetomidine has a neutral effect.[267] Midazolam given during extinction training, which normally inhibits learned fear expression, blocks the effect of extinction,[261] and also blocks fear-reducing effects when given during preconditioning contextual learning.[268] When sevoflurane is administered at a very low, nonsedating dose (0.11%), fear conditioning is enhanced.[269,270]

STUDIES OF ANESTHETIC EFFECTS ON FEAR SYSTEMS IN HUMANS

Three functional neuroimaging studies have directly addressed anesthetic effects on emotional memory. A study using PET and path analysis (Fig. 9.5 *lower panel*)[271] demonstrated that the superior memorability that negatively arousing emotional items have over neutral items was unaffected by 0.1% and 0.2% sevoflurane, but lost at 0.25%, and was associated with decreased effective connectivity projecting from the right amygdala to hippocampus, and also from the right nucleus basalis to hippocampus. Further, sevoflurane modulated emotional perception such that items were rated more neutrally. An fMRI study demonstrated that sedative doses of propofol do not reduce activation of the amygdala in response to negatively arousing items, but activation of the hippocampus is markedly attenuated (see Fig. 9.5 *upper panel*) and correlates with amnesia and loss of the superior memorability of emotional material.[218] This suggests that cortical and subcortical processes serving emotional interpretative functions and afferent amygdala activation are relatively spared by amnestic levels of propofol, while efferent processes underlying amygdala-dependent modulation of hippocampal plasticity are interrupted. An fMRI study of dexmedetomidine also reported no effect on activation of the amygdala in response to negatively arousing items,[216] but in contrast to propofol, emotional items retained superior memorability, and activation in the left amygdala and hippocampus were correlated with subsequent memory. Taken together, these studies imply that propofol may have a more targeted effect on the amygdalo-hippocampal modulatory axis. One potential explanation is that amygdalo-hippocampal connectivity is markedly interrupted by a loss of theta oscillatory synchrony caused by propofol, whereas α_{2A} antagonism at the LC causes only limited downstream attenuation of noradrenergic signaling in the BLA.

CLINICAL RELEVANCE

Amygdala reactivity is of importance in a number of fear-based psychopathologies, including anxiety, phobia, panic disorder, and PTSD.[272] The neurohumoral stress response to surgery and critical illness can cause complex changes in levels of catecholamines, glucocorticoids, and other potential promoters of plasticity in amygdala-dependent fear processes, occurring within a context that frequently contains emotional stressors. It is unclear under what specific conditions elevated (or depressed) levels of these mediators might contribute to long-term changes in neuropsychological functioning, although multiple studies in the critical care setting relate stress exposure, and exogenous administration of catecholamines, to negative long-term outcomes.[273] In a broad surgical population, the incidence of PTSD-complex symptoms related to surgery was reported to be 16%[5]—similar to that observed in victims of violence. The effect—or lack of effect—of anesthetic drugs on plasticity processes in the perioperative or critical care setting thus has a theoretical potential to impact long-term psychological sequelae, both positively and negatively. However, there is presently insufficient human data to inform specific recommendations.

Anesthetic Effects on Implicit Memory Function

Implicit (nondeclarative) memory processes do not axiomatically require a conscious substrate, and are not dependent on classic hippocampal plasticity. Therefore the effect of anesthetic drugs on implicit memory functions may have important distinction from those on declarative memory, and accordingly a number of investigations have sought evidence for implicit processing in unconscious subjects. Many studies have used auditory adaptations of the *word stem completion task*, or the more rigorous *process dissociation procedure*, in which subjects are asked to exclude items that have been presented; declarative memory will drive avoidance of the target word, while implicit memory will lead to a familiarity response favoring the target word.

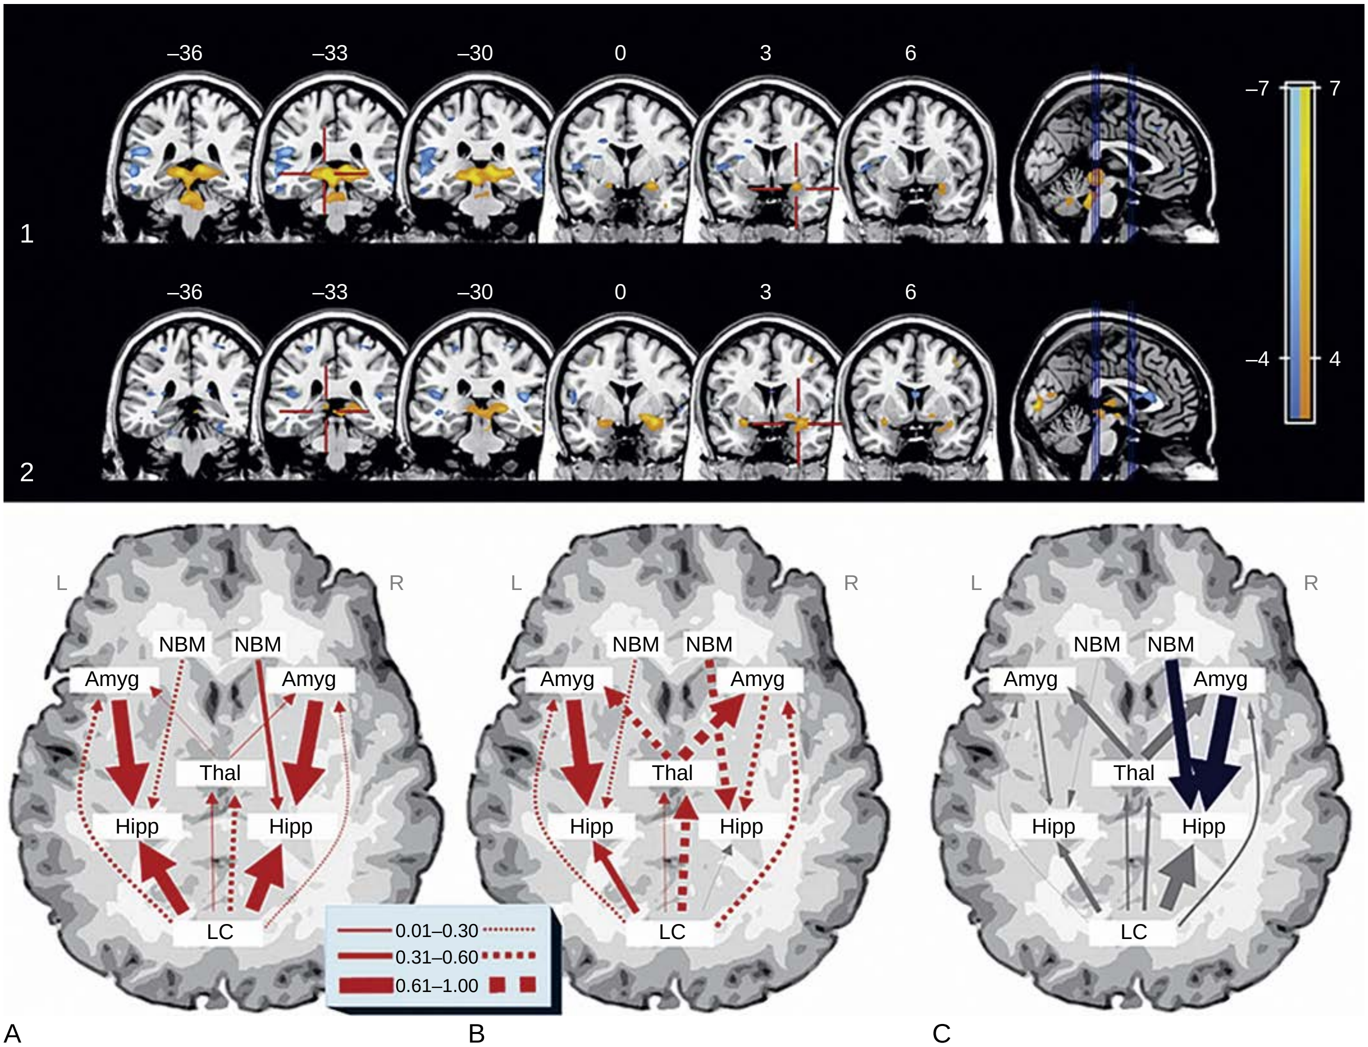

Fig. 9.5 Anesthetic effects on emotional memory systems. (*upper panel*) Functional magnetic resonance imaging scans showing the contrast in response to negatively arousing items relative to neutral items, with coronal slices through the amygdala (0, 3, 6) and hippocampus (–30, –33, –36). The control condition *(top row)* shows enhanced activation of both the amygdala and hippocampus in response to the added emotional information, while in subjects receiving propofol *(bottom row)* there is enhanced activation of the amygdala, but not of the hippocampus. (*lower panel*) Path diagrams of connectivity at rest, with positive influences of one region onto another shown as solid lines, negative influences shown as dotted lines, and width representing magnitude. In the control condition *(A)* there is a significant positive influence of the amygdala onto the hippocampus bilaterally. Administration of sevoflurane 0.25% *(B)* blocks emotional modulation behaviorally, and removes the positive influence of the right amygdala and nucleus basalis of Meynert on the hippocampus. Numerical differences in path weight *(C)* show these two paths to significantly contribute to the network model more in the control than sevoflurane state. *Amyg,* Amygdala; *Hipp,* hippocampus; *LC,* locus ceruleus; *NBM,* nucleus basalis of Meynert; *Thal,* thalamus. ([A] Modified from Pryor KO, Root JC, Mehta M, et al. Effect of propofol on the medial temporal lobe emotional memory system: a functional magnetic resonance imaging study in human subjects. *Br J Anaesth.* 2015;115[suppl 1]:i104–i113, Figure 3; [B] Modified from Alkire MT, Gruver R, Miller J, et al. Neuroimaging analysis of an anesthetic gas that blocks human emotional memory. *Proc Natl Acad Sci U S A.* 2008;105[5]:1722–1727, Figure 5.)

Two early studies in patients undergoing coronary artery[274] and gynecologic[275] procedures showed evidence of implicit learning using word stem completion tasks. Another early study demonstrating implicit recall in cardiac surgery patients correlated performance with preservation of the midlatency auditory evoked potential, and most strongly with the early cortical Pa and Na complexes.[276] Later studies demonstrated implicit memory in both trauma patients[277] and patients undergoing an emergency cesarean section[278] using the process dissociation procedure, and further demonstrated that the degree of processing is related to the bispectral index. However, multiple more recent studies using similar procedures have either failed to show significant implicit priming effects or have been equivocal.[279-281] Synthesis of these disparate results into a cohesive conclusion is difficult. Although differences in patient populations and anesthetic regimens may be of relevance, methodological challenges may have driven both false positive and false negative results. Investigations evaluating implicit memory processes in pediatric patients under anesthesia have also offered conflicting results. One study reported an increased ability to distinguish a primed animal sound from white noise,[282] but other investigations found no evidence of priming.[283–285]

10 Sleep Medicine

MATTHIAS EIKERMANN and SEBASTIAN ZAREMBA

KEY POINTS

- Sleep is a dynamic neuronal and behavioral state that can be characterized using specific electroencephalographic, electrophysiologic, and behavioral findings.
- Characteristics of sleep can be quantified using questionnaires, actigraphy, or respiratory polygraphy. However, polysomnography, including electroencephalogram, electrooculogram, submental electromyogram, and analysis of breathing, is required to describe the cortical characteristics and immediate physiological consequences.
- Activation of hypothalamic sleep-promoting pathways including the ventrolateral preoptic nucleus and the median preoptic nucleus produces the physiological switch from wakefulness to sleep.
- Sleep and anesthesia can look similar. Although small doses of anesthetics can induce sleep by activating sleep-promoting pathways, surgical anesthesia and immobilization cannot be induced by sleep-promoting pathways.
- Control of breathing is altered during sleep and anesthesia, typically leading to a decreased drive to upper airway dilator and respiratory pump muscles.
- Persistent respiratory depressant effects of anesthetics and neuromuscular blocking drugs increase the risk of postoperative respiratory complications, particularly in patients with obstructive sleep apnea.
- Anesthesia and surgery, as well as treatment in the intensive care unit and opioids, affect sleep duration and sleep architecture, which may lead to impaired outcome.

Probably the earliest mention of “overpowering sleep” as a metaphor describing what possibly characterizes anesthesia can be found in Genesis 2:21: “And the Eternal God caused an overpowering sleep to fall upon the man and he slept. He took one of his ribs and shut in flesh instead thereof.” Although this “overpowering sleep” allegedly occurred by divine intervention and did not represent the drug-induced unconsciousness and immobility that characterizes anesthesia, the basic narrative is an example of antiquarian history that implicates the concept that deep sleep may be the only viable condition that allows a surgical procedure to be completed successfully.[1]

In the 21st century, an increasing body of knowledge has revealed the common ground between sleep and anesthesia, as well as their fundamental differences in clinical picture and underlying mechanisms.

Sleep is required for survival. Rats deprived of sleep will die within 2 to 3 weeks, a time frame similar to death due to starvation.[2] In humans, sleepiness can be deadly. Approximately 100,000 motor vehicle accidents each year result from drivers who are “asleep at the wheel.” In a survey of drivers in New York State, approximately 25% reported they had fallen asleep at the wheel at some time.[3] In addition, sleep deprivation impairs the psychomotor performance of night shift workers, specifically surgeons and residents. In patients, perioperative sleep deprivation occurs frequently, particularly in critically ill patients, and there may be consequences on patients’ outcomes. Among sleep disorders, obstructive sleep apnea (OSA) has probably the most meaningful consequences for perioperative treatment.[4]

Therefore, high-quality physiologic sleep is a key domain of public health that needs to be considered in perioperative medicine from both a provider and a patient perspective.

Definition of Sleep

Sleep is the natural periodic suspension of consciousness during which the powers of the body are restored. A behavioral definition of sleep includes a species-specific posture and behavioral quiescence, as well as elevated arousal thresholds. However, sleep is much more than an absence of activity. The brain is highly active during sleep, especially during rapid eye movement (REM) sleep, during which atonia, phasic muscle movements (driven by different activation levels in distinct areas of the brain), and vivid dreaming occur. Sleep is not a simple electrophysiological phenomenon. At different stages of sleep, brain activities can be as distinct from each other as they are from wakefulness.[5] In humans and other vertebrates (see “Evolution”), sleep has two major stages: REM sleep and non-REM (NREM) sleep, with each of these further divided into substates. Most of sleep time is spent in NREM sleep, which is characterized by relatively low electroencephalographic (EEG) frequencies with higher amplitudes compared with awake EEG frequencies (Fig. 10.1). In the transition from wake to NREM sleep, the fast activity of waking disappears (α–θ transition), and then in the deeper stages of NREM large, slow waves (i.e., δ waves) emerge. Thus deep NREM sleep is also referred to as *slow-wave sleep*. NREM sleep is associated with waxing and waning muscle tone, as well as decreased body

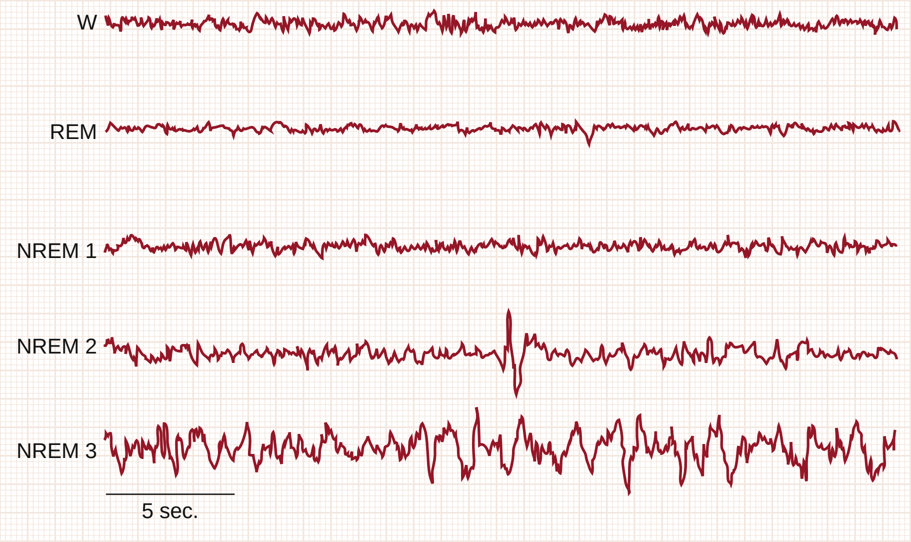

Fig. 10.1 Representative electroencephalogram activity seen during different behavioral states. Electroencephalogram recordings of one patient during wakefulness (eyes closed; *W*), rapid eye movement sleep *(REM)*, and non-REM *(NREM)* sleep stages 1 to 3.

temperature and heart rate. In contrast, REM sleep is characterized by muscle atonia, loss of slow waves in the EEG, and bursts of REMs that give this state its name.[6] Other prominent features of REM include marked irregularities of respiration and heart rate, as well as penile and clitoral erection. REM sleep is associated with the high likelihood of vivid dreaming. A distinct property of REM sleep is the operation of a system that suppresses motor activity, which is responsible for baseline atonia and suppression of motor commands that would otherwise result in acting out of dreams, a phenomenon known as *REM sleep behavior disorder*. This REM atonia system is not constant, as it periodically allows breakthrough muscle activity that comprises REM sleep and twitching of the extremities. REM sleep has therefore been subdivided into *tonic REM sleep* (i.e., a period with muscle atonia and without eye movements) and *phasic REM sleep*, which is interrupted by short phasic events of the eye and other movements.[7] The pattern and amounts of NREM sleep, REM sleep, and wakefulness throughout the night are referred to as *sleep architecture*, and there are many physiologic and pathophysiologic processes that can affect sleep architecture. For example, many antidepressant medications, benzodiazepines, and opioids selectively suppress REM sleep. A disease example is narcolepsy, in which individuals often transition rapidly from wake to REM, whereas normally REM is nearly always entered from a prolonged episode of NREM state.

Physiology

EVOLUTION

It is unknown why we sleep; however, one can imagine that evolutionary pressure would favor systems that are optimized for nature's rhythms.[8,9] In a rhythmic world, organisms must adapt to alternating changes in the environment, such as daily and seasonal rhythms in light intensity, ambient temperature, and humidity.

CIRCADIAN RHYTHMS

Species-dependent temporal behavior can be adapted depending on the environmental conditions: behaviorally, anatomically, and physiologically. Circadian rhythms affect almost every aspect of the body's function, including activity and rest patterns, cognitive function (e.g., learning and memory), cardiovascular and endocrine physiology (e.g., heart rate, metabolism, and hormone secretion), and gene expression (15% of the genes in the human body show daily rhythms).

Virtually all species show circadian rhythms that regulate periodic changes in behavioral and physiologic parameters within a period of approximately 24 hours.[10] These rhythms can be characterized as a synchronization of activity to the external light-dark cycle in the majority of living creatures. Bacteria, plants, animals, and humans exhibit such a behavior that helps them stay in tune with the environmental light-dark cycles.[11] Our sleep timing preference, or chronotype, is a manifestation of our internal biological clock. Variation in chronotype has been linked to sleep disorders, cognitive and physical performance, and chronic disease.[12]

Clock genes generate endogenous clock pulses in most (if not all) cells of the body, synchronized by regulatory pathways across the body to a superior rhythm generator (a so-called master clock). Desynchronization of these rhythms seems to be involved in the pathogenesis of metabolic, psychiatric, and other disorders.[11] The superior rhythm generator in humans is located in the suprachiasmatic nucleus that receives external inputs about light and darkness from the retinal cells and synchronizes inputs of melatonin levels. While this master clock synchronizes the behavioral and biological rhythms of the human body to the changing demands of the environment during the solar day, sleep itself entrains circadian rhythms,[11,13] and the temporal organization of circadian rhythms and nocturnal sleep must be preserved to accomplish a restful and refreshing experience that fulfills the sleep needs produced by the

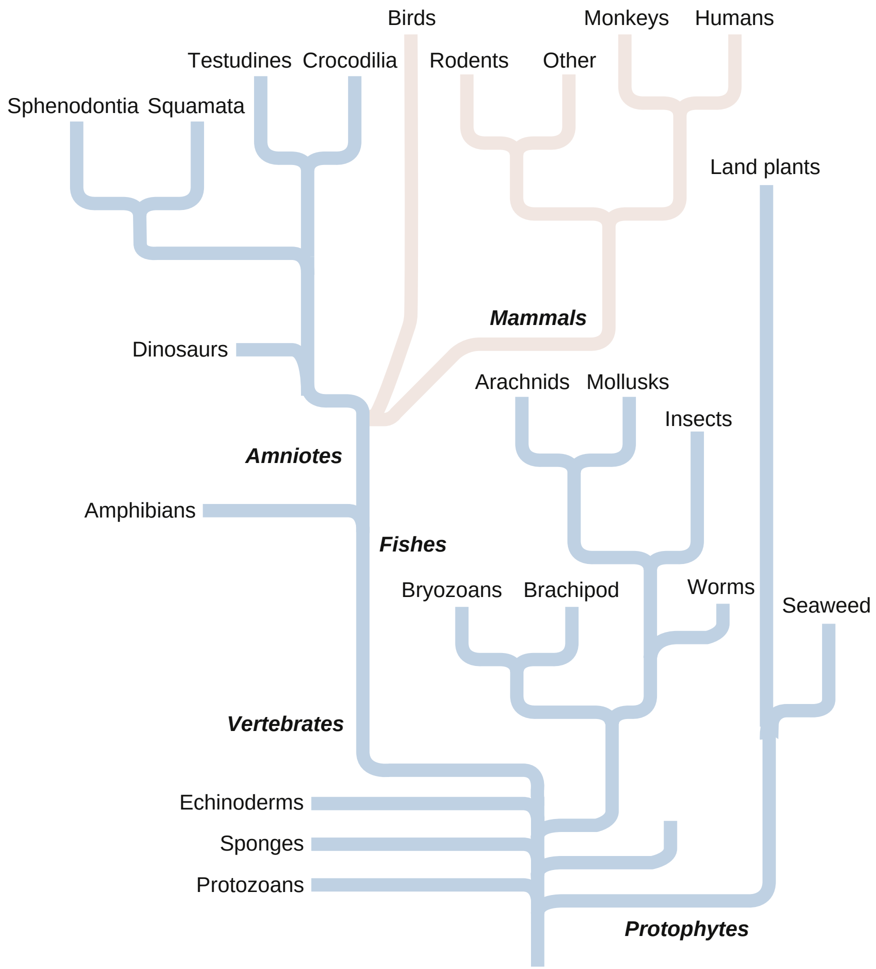

Fig. 10.2 Evolutionary tree. Circadian rhythms are common among all living beings. However, only mammals and birds *(red)* have integrated sleep with different stages. Fish, reptiles, insects, and plants *(blue)* manifest circadian rhythms as periods of activity and rest.

second major regulatory factor, sleep homeostasis. During waking, "sleep pressure" continuously increases, leading to an increased likelihood for the transition from wakefulness to sleep.[14] Increasing homeostatic sleep pressure can be partly offset by a sufficient circadian wakening stimulus during the circadian wake phase, but the circadian wake stimulus disappears in the presence of an overwhelming sleep pressure.[15] In this situation, sleep sufficient in quantity and quality is needed to reestablish proper functioning.

Although circadian and homeostatic regulation of sleep can be observed in almost all living organisms,[16] differentiation of sleep into NREM and REM sleep ("integrated sleep") probably has developed during the last 300 to 350 million years because it appears only in birds and the majority of terrestrial mammals (Fig. 10.2).[17,18]

Sleep Stages and Sleep Cycles

Sleep architecture—a structured temporal order of different sleep stages—is an important determinant of sleep quality. If tired individuals rest in their individual sleeping postures, the increasing level of drowsiness is paralleled by continuous EEG slowing from that seen during attention and cortical activation (16-30 Hz, "β activity") to slower frequencies, predominantly between (7.5 and 11 Hz, "α activity," typically observed in subjects with reduced attention and closed eyes). During this state of vigilance, the individuals do not sleep, and a full level of cognitive function can be established easily even without a strong sensory stimulus. The transition from α state to sleep is paralleled by a further decrease in α and β activity and an increase of EEG activity in the θ band (4.5-7.5 Hz; Fig.10.3).

This transition from α to θ activity is widely accepted as the EEG correlate of sleep onset.[19] At this transition from wakefulness to NREM sleep stage 1, heart rate and heat production decrease, resulting in a slight decrease in body temperature. Furthermore, respiration is regular and deep. As sleep deepens, EEG activity shows low amplitudes and θ activity with intermittent sleep spindles and K-complexes. The latter represents an activation of brainstem and subcortical brain areas during sleep[20,21] for selective processing of unexpected sensory inputs (e.g., sounds) that might require complete arousal and restoration of consciousness to address a potential threat.[22] In accordance with that hypothesis, in comatose patients with brain injury, the presence of K-complexes in response to an acoustic stimulus during coma seems to be a marker of a better outcome compared with comatose patients with no evoked K-complexes.[23] With increasing depth of sleep, during NREM sleep, electrical activity of the cortex measured by EEG is dominated by slower frequencies and high amplitudes, also referred to as *slow-wave sleep*.

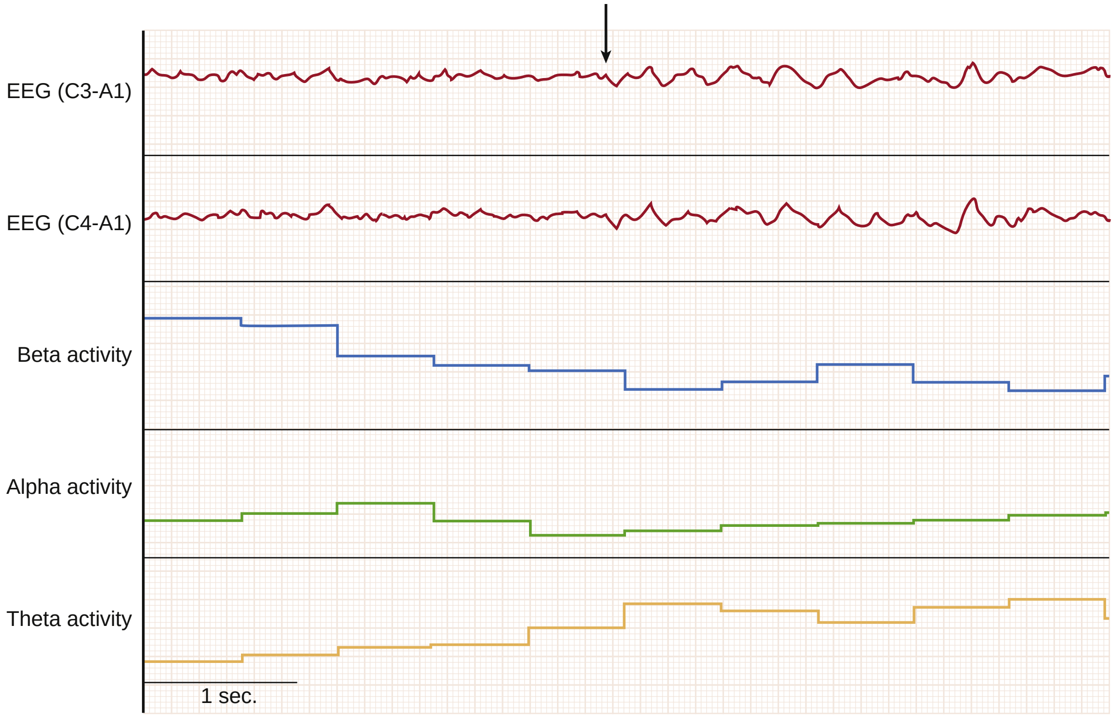

Fig. 10.3 Electroencephalogram recording during sleep onset *(arrow)*. The two top rows show bipolar electroencephalogram *(EEG)* signals from left (C3-A1) and right (C2-A1) frontal leads. Rows 3 to 5 show the relative amount (EEG power) of β, α, and θ activity calculated using fast Fourier transformation.

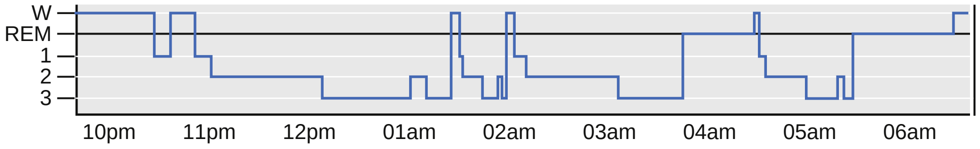

Fig. 10.4 Hypnogram of a night of physiologic sleep. During one night (time on x axis) of sleep, humans transition repetitively from one sleep stage to another with short episodes of occasional wakefulness (indicated on y axis). *REM,* Rapid eye movement sleep; *W,* awake; *1*, non-REM sleep stage 1; *2*, non-REM sleep stage 2; *3*, non-REM sleep stage 3 (slow wave sleep).

REM sleep, or paradoxical sleep, is associated with an alteration of homeostatic regulation, such as increased heart rate variability, irregular respiration, and impaired body temperature control. Brain metabolism increases while EEG recordings show similarities to wakefulness with low-voltage and mixed-frequency power spectra. Prominent θ waves generated by the hippocampus occur. These waves are not apparent in the scalp EEG recording from humans, but in rodents, in which the hippocampus is larger and closer to the brain surface, the EEG is dominated by θ during REM. This sleep state is associated with a decreased tone in skeletal muscles (except for extraocular muscles that control eye movement). Dreaming is a typical experience during REM sleep,[24] but can also happen during NREM sleep.[25] During physiologic sleep, an individual typically switches back and forth across sleep stages, interrupted by occasional arousals from sleep (Fig. 10.4).

NEUROANATOMY OF SLEEP

Sleep-Promoting and Arousal Pathways

Several neuronal pathways have evolved to maintain cortical activation and behavioral arousal during normal waking, and others have evolved to promote and maintain sleep (Fig. 10.5). It is the balance between these two systems that determines whether one is awake or asleep.

Ascending Arousal System. The ascending arousal system (AAS) is the main wakefulness-mediating network in the brain. Main pathways within the network receive cholinergic, monoaminergic, dopaminergic, and glutamatergic inputs. Cholinergic inputs originate from pedunculopontine and laterodorsal tegmental nuclei, innervate the lateral hypothalamus, prefrontal cortex, basal forebrain, and thalamic relay nuclei (i.e., medial and lateral geniculate nuclei; mediodorsal nucleus; pulvinar; anterior, ventral, and lateral thalamic cell groups).[26,27] Glutamatergic neurons that provide inputs to the AAS are mainly located within a small area just ventral of the locus ceruleus (LC), the preceruleus area, as well as in the parabrachial nuclei that mainly project to the basal forebrain and the lateral hypothalamus.[28,29] Monoaminergic inputs mainly come from noradrenergic neurons within the LC, histaminergic neurons of the tuberomammillary nuclei (TMN), serotoninergic neurons of the median and dorsal raphe nuclei,[30,31] as well as dopaminergic neurons adjacent to dorsal raphe nuclei.[24,32] Beside projections to the basal forebrain, multiple inputs are sent to the thalamus, mainly the interlaminar

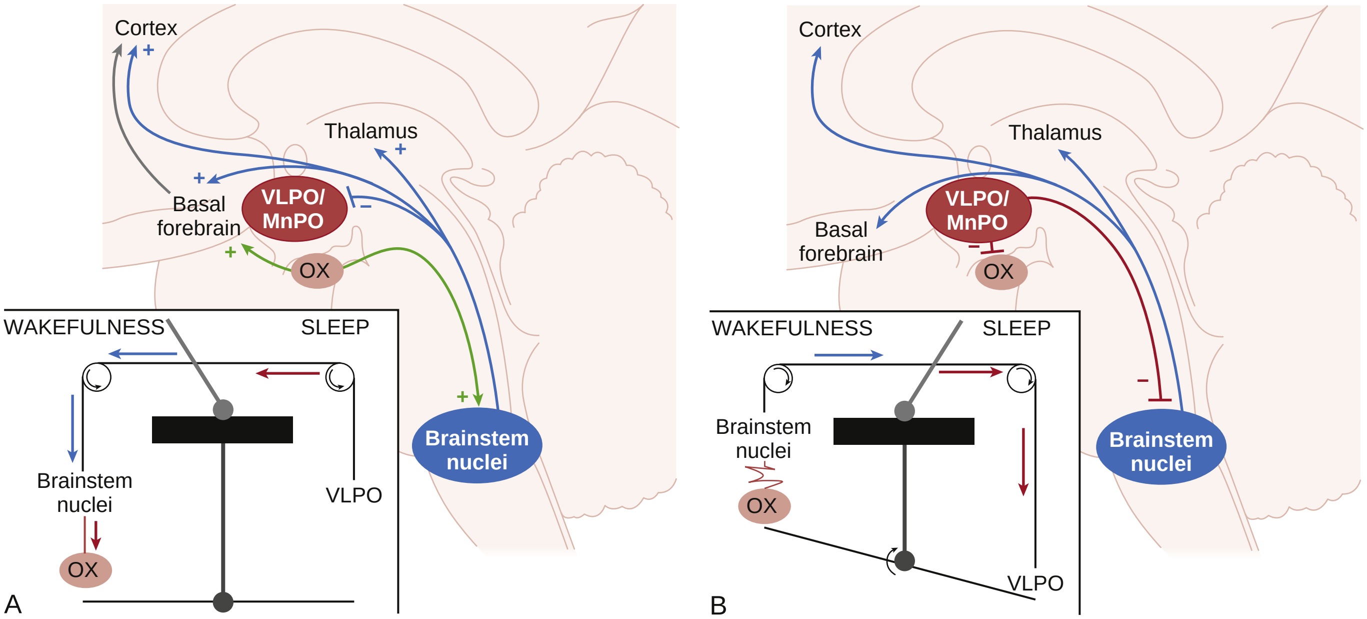

Fig. 10.5 Flip-Flop switch ensuring rapid transitions between wakefulness and sleep. During wakefulness (A), brainstem nuclei of the ascending arousal system (AAS) directly and indirectly provide excitatory input to the thalamus, basal forebrain, and the cerebral cortex, while they inhibit the ventrolateral *(VLPO)* and median *(MnPO)* preoptic nuclei (switch flips to wakefulness). The excitatory, wake-promoting stimulus is enforced by additional excitatory input of orexinergic neurons *(OX)* to the BF and the AAS. During sleep (B), neurons of VLPO and MnPO inhibit the brainstem and orexinergic neurons of the AAS (switch flops to sleep). (Modified from Saper CB, Scammell TE, Lu J. Hypothalamic regulation of sleep and circadian rhythms. *Nature.* 2005;437:1257–1263; and Saper CB, Fuller PM, Pedersen NP, Lu J, Scammell TE. Sleep state switching. *Neuron.* 2010;68:1023–1042.)

and reticular nuclei, as well as the amygdala and cerebral cortex. Furthermore, noradrenergic neurons of the LC project mainly to the posterior part of the lateral hypothalamus. In return, the latter area of the lateral hypothalamus projects to the LC and to the TMN.

Some neurons of the posterior hypothalamus produce orexin A and B, also known as hypocretin (HCRT) 1 and 2. These neurons project to the basal forebrain and the amygdala and cerebral cortex and other important arousal areas, and they are essential for stabilizing the waking state.[32] Orexin deficiency causes narcolepsy (severe daytime sleepiness) with cataplexy (abrupt loss of muscle tone),[33] a disorder showing some characteristics of REM sleep (i.e., REM sleep atonia during wakefulness [discussed later]).

Orexin System. Orexin and its cognate receptors (OX_1R and OX_2R) play a key role in sleep/wake regulation. This neurotransmitter system has a crucial involvement in the pathogenesis of narcolepsy, a disorder associated with chronic excessive daytime sleepiness, sleep attacks, and rapid transitions between vigilance states and sleep in humans.[34] Studies in mice recapitulating the narcolepsy phenotype by targeted mutagenesis of the HCRT gene encoding the prepropeptide precursor of orexin neuropeptides,[35] or the less pervasive phenotype of OX_2R knockout mice,[36] not only demonstrated the role of orexin signaling in sleep/wake regulation but also demonstrated biological proof of concept for the development of orexin receptor antagonists for the treatment of insomnia. In contrast, the activation of orexin pathways, either by exogenous administration of orexin receptor agonists or by optogenetic activation of orexinergic neurons in the lateral hypothalamus, increases arousal.[37,38] Orexinergic neurons are counteracted by inhibitory γ-aminobutyric acid (GABA)-ergic neurons originating from the ventrolateral preoptic nucleus (VLPO). OX_2R is expressed exclusively in the histaminergic TMN, whereas OX_1R is expressed preferentially in the noradrenergic LC, and both receptors are present in cholinergic pedunculopontine and laterodorsal tegmental nuclei.[38,39] Orexinergic tone at these hypothalamic and brainstem nuclei contributes to cortical arousal.[40] TMN, the predominant source of histamine in the brain responsible for cortical arousal, receives a prominent projection from orexinergic neurons[40,41] mediated predominantly by OX_2R. Orexin receptor antagonists promote sleep mainly via inhibition of the OX_2R receptor.[42-45]

Non-Rapid Eye Movement Sleep-Promoting Pathways. About 100 years ago during the epidemic of encephalitis lethargica, it was observed that lesions in the preoptic region around the rostral end of the third ventricle were associated with profound insomnia,[46] which was confirmed in neuroanatomic experiments (lesion studies) in rats and cats.[47,48] Neurons in the preoptic area are active during sleep.[49-51] Two key nuclei within this area are the VLPO as well as the median preoptic nucleus. VLPO neurons fire at a higher frequency during sleep compared with wakefulness.[52] Anatomically, the VLPO consists of a dense core of sleep-active, galanin-positive neurons innervating the TMN (which is part of the AAS) while being surrounded dorsally and medially by a more diffuse population of sleep-active, galanin-positive neurons that project to the dorsal raphe and LC.[53] Physiologically, the VLPO neurons constitute a sleep-promoting pathway that inhibits many components of the arousal system during sleep. Likewise, parts of the arousal system such as the laterodorsal tegmental nucleus and the pedunculopontine tegmental nucleus, as well as the LC, the parabrachial nucleus, the dorsal raphe nucleus, the PC, the ventral periaqueductal gray, and the TMN, are capable of inhibiting the VLPO. The mutually inhibitory relationship of the arousal and sleep-promoting pathways produces the conditions of a flip-flop switch, which can generate rapid and complete transitions between waking and sleeping states (see Fig. 10.5).[53,54] It also makes simultaneous activation of arousal and sleep circuits highly improbable.

Because animal experiments showed that even large lesions of the VLPO substantially reduce but do not completely erase sleep, other brain areas beside this nucleus are likely involved in promoting sleep.[55] Several basal forebrain areas,[49,51] as well as some GABA-ergic interneurons across the cerebral cortex,[56] have been implicated to function as sleep-active neurons. Nevertheless, the role of these brain regions in the promotion or regulation of sleep remains unclear.

Rapid Eye Movement Sleep-Promoting Pathways and Non-Rapid Eye Movement–Rapid Eye Movement Transition. During normal sleep that presents at onset as a sharp α–θ EEG activity transition, a similar sharp transition from NREM to REM sleep can be observed. Two groups of mutually inhibitory neurons located in the pons are involved in mediating the switch between NREM and REM sleep.[28] The first group consists of REM active inhibitory neurons of the sublaterodorsal nucleus and the PC region.[29,54,57] These neurons inhibit but are also inhibited by a second group of neurons that are located in ventrolateral periaqueductal gray and adjacent lateral pontine tegmentum. This mutually inhibitory relationship produces a REM-NREM flip-flop switch, promoting rapid and complete transitions between sleep states.[54]

Within the sublaterodorsal nucleus and PC, glutamatergic neurons are mixed within the population of REM-on GABA-ergic neurons. The glutamatergic sublaterodorsal nucleus neurons project to the spinal cord and are important for REM sleep atonia; the glutamatergic PC neurons activate forebrain pathways driving EEG desynchronization and hippocampal θ rhythms—characteristic EEG signs of REM-sleep.[58]

How to Assess Sleep

The complexity of signs and symptoms of sleep suggests that different instruments need to be applied to capture all the important elements of sleep.

QUESTIONNAIRES

Several questionnaires are used for the assessment of sleep duration, sleep quality, and the related physiologic and pathophysiologic consequences. Quality of sleep is a frequent target of generic health surveys for measuring patient-reported outcomes. Other questionnaires quantify the consequences of sleep deprivation, specific sleep disorders, or both (Table 10.1). The most commonly used instrument in sleep medicine is probably the Epworth Sleepiness Scale, a short questionnaire to assess symptoms of daytime sleepiness, expressed as intolerance to monotony. The questionnaire asks the subject to rate the probability of falling asleep on a scale of increasing probability from 0 to 3 for eight different situations, such as such as watching TV, reading, lying down in the afternoon, and so on.[59] Despite the fact that the Epworth Sleepiness Scale

TABLE 10.1 Sleep Questionnaires: Questionnaires Commonly Used for Clinical and Research Purposes and Their Focus

Questionnaire*	Focus	References
Pittsburgh Sleep Quality Index (PSQI)	Sleep and sleep disorders	60,61
Sleep Quality Scale (SQS)	Sleep quality	66
Functional Outcome of Sleep Questionnaire (FOSQ)	Impact of daytime sleepiness on daily living	12,67

is reliable for detection of daytime sleepiness,[60,61] the instrument does not determine the mechanism of daytime sleepiness.[62,63]

Other clinically useful questionnaires that focus on the detection of signs and symptoms of sleep disorders are available,[59-79] which is important because the prevalence of sleep pathologies typically varies in a wide range across populations (see Table 10.1).

An effective process for clinical assessment of sleep-related diseases is a stepwise assessment using a screening tool first (e.g., Epworth Sleepiness Scale), followed by a more specific questionnaire that helps identify individual mechanisms or consequences of sleepiness.

A special form of sleep questionnaires comes in the form of sleep diaries and "morningness-eveningness" questionnaires that evaluate daily sleep habits, including sleep time, sleep duration, number of nocturnal awakenings, and subjective sleep quality.[80]

Although questionnaires allow a quick and easy screening for daytime symptoms of sleep disturbances, they do not quantify sleep architecture. Subjective methods of assessing sleep are influenced by the spectrum of disease within a tested group, actual clinical change over time, the testing conditions, and recall bias.[80] Clearly, a questionnaire cannot replace a medical history or objective assessment for sleep disorders. However, sleep questionnaires are important tools for measuring health improvement or decline, predicting medical expenses, assessing treatment effects, or comparing disease burden across populations.

ACTIGRAPHY

Actigraphy is used to study sleep-wake patterns by detecting motion of the wrist with linear accelerometers in single or multiple axes. Based on movement-derived data, predictions of the time spent during sleep and wakefulness can be made, and even assumptions on sleep staging are made. Actigraphy can be used conveniently in a patient's home for several nights, weeks, or longer,[81] but its validity for detecting transitions from wakefulness to sleep has been debated, especially in patients with high levels of sleep fragmentation.[81,82] In the clinical setting, actigraphy has been used to evaluate sleep patterns in patients with insomnia, for diagnosis of circadian rhythm disorders (including shift work), and in evaluating sleep in individuals who are less likely to tolerate polysomnography (PSG), such as infants and demented elderly. However, its accuracy is limited for patients with reduced mobility, such as nursing home or intensive care unit (ICU) patients. Actigraphy allows for convenient follow-up measurements to evaluate the effects of treatments designed to improve sleep architecture and circadian rhythm disorders.[83] In more recent years, an increasing number of wearable devices for the detection and analysis of activity and rest have been marketed. Although some have claimed to detect sleep accurately, as well as some sleep stages (mainly REM sleep),[84] none of the current models are yet approved or validated for clinical use.

RESPIRATORY POLYGRAPHY

Home respiratory polygraphy (RP) can be a cost-effective alternative to PSG for the diagnosis of sleep apnea-hypopnea syndrome. RP usually calculates airflow through nasal pressure changes taken via nasal cannulae. Thoracic and abdominal movements are measured by piezoelectric bands, which also measure body position and blood oxygen saturation by pulse oximetry. Using these parameters, RP can identify apnea and hypopnea, and categorize the pathophysiology of apnea into obstructive versus central. Furthermore, similar to actigraphy, RP provides some analysis of sleep duration and time spent awake, using its body position and light sensors. However, the quality of the latter can be more precisely evaluated by a combination of sleep diary and actigraphy. Nevertheless, EEG is required to decide whether a subject was awake or sleeping (Table 10.2).

TABLE 10.2 Pros and Cons of Different Methods of Sleep Evaluation

Method	Pros	Cons	Recommendation
Sleep questionnaire	Low cost Good compliance Easy to use	Recall bias Limited reliability in some populations Limited validity	Should be combined with interview
Sleep diary	Less recall bias Easy to administer Low cost Documentation of daily variability	Lower compliance compared with other questionnaires Biased by daily mood and expectations on sleep	Should be combined with other measurement of sleep duration (e.g., actigraphy)
Actigraphy	Provides objective information about daily variability and sleep duration Provides information on sleep habits at home Not influenced by patient expectations, recall bias, or memory impairments Lower cost than laboratory polysomnography	Limited assessment of sleep stages and sleep onset latency Higher cost than questionnaires	Should be combined with other measurement of sleep duration (e.g., sleep diary)

Continued

TABLE 10.2 Pros and Cons of Different Methods of Sleep Evaluation—cont'd

Method	Pros	Cons	Recommendation
Polygraphy	Lower cost than laboratory polysomnography Objective assessment of respiratory events Provide information on sleep habits at home	Limited assessment of sleep Higher cost than questionnaires Limited assessment of sleep disorders other than sleep-disordered breathing	Should be accompanied by questionnaires and clinical interview
Laboratory polysomnography	Objective assessment of sleep, sleep stages, and sleep disorders	High cost First-night effect Limited capacity No information about sleep habits at home	Should be last step in sleep evaluation with previous questionnaires and ambulatory screening (e.g., polygraphy)
Out-of-center polysomnography	Objective assessment of sleep, sleep stages, and sleep disorders Less first-night effect Lower cost than laboratory polysomnography Can provide information about sleep habits at home	Limited observation may lead to decreased recording quality	Good patient education mandatory If possible, surveillance recording preferred

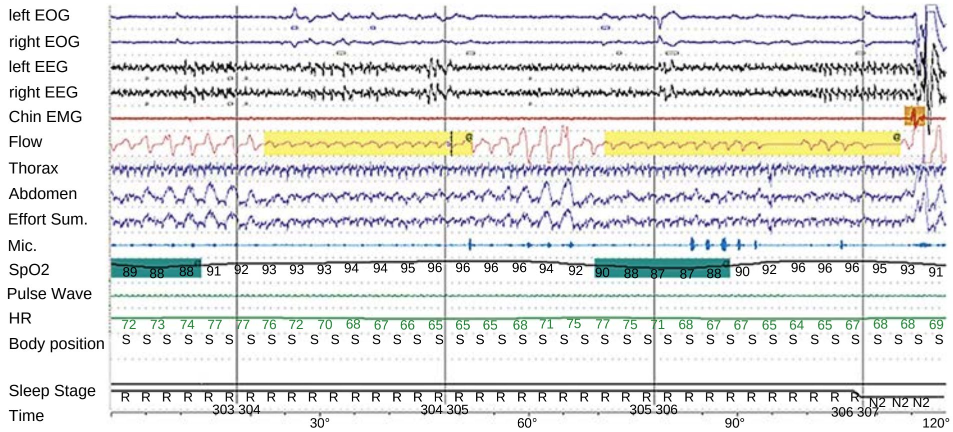

Fig. 10.6 Polysomnographic recording. Left and right electrooculogram *(EOG)*, two electroencephalogram *(EEG)* channels, and mental electromyogram *(Chin EMG)* allow scoring of sleep stage (REM sleep [R] with typical eye movements in the electrooculogram channels). Additional channels (e.g., respiratory flow *[Flow]*, respiratory effort of thorax *[Thorax]* and abdomen *[Abdomen]*, microphone *[Mic.]* oxygen saturation *[SpO_2]*) allow diagnosis of sleep disordered breathing. In this patient, apneas *(yellow boxes)* led to oxygen desaturation *(blue boxes)* and finally to arousal *(far right, brown box)*.

POLYSOMNOGRAPHY

PSG is the only method that can precisely determine the actual sleep stage and is a reference diagnostic tool (i.e., gold standard) that is required for the diagnosis of several sleep disorders.[85] PSG measurements include EEG, electrooculography for the measurement of eye movements, and at least electromyographic measurement of muscle activity of the chin.[86] These three measurements are typically supplemented by other channels for the detection of sleep-disordered breathing (SDB), such as a nasal sensor to detect apneas and hypopneas, oximetry, inductance plethysmography for respiratory effort of the chest and abdomen, and a body position sensor and leg electromyogram[87] to identify periodic limb movement syndrome or REM sleep behavior disorder, respectively.[88] A typical PSG recording is shown in Fig. 10.6.

Sleep Laboratory Testing

For several decades, PSG was performed only within a sleep laboratory. Sleep laboratory PSG is attended by a trained technician and is analyzed by a clinician trained in sleep medicine according to the published guidelines.[87,89-91] However, the high cost and requirement of an overnight stay can present socioeconomic challenges that affect the accessibility of this method. In-center PSG provides only a momentary view of the patient's sleep, and the measurements themselves can impair patients' sleep (the so-called first-night effect) and does not provide information about sleep at home. Multiple repeated measurements to tailor treatment over time are challenging or even impossible from a logistic and healthcare economics perspective. Therefore, an increasing number of out-of-center devices

TABLE 10.3 Polysomnographic Characteristic of the Different Behavioral States

	EEG and EOG Characteristics	AASM
Wakefulness	α rhythm (8-13 Hz) present in more than 50% of an epoch	W
Non-REM sleep stage 1	Lower amplitudes and activity in range of 4-7 Hz (vertex sharp waves,* slow eye movements*)	N1
Non-REM sleep stage 2	EEG of sleep stage 1 with additional a sleep spindles and K-complexes; slow waves not fulfilling the criteria for sleep stage 3	N2
Non-REM slow wave sleep	20%-50% of slow wave activity (0.5-2 Hz)	N3
REM sleep	EEG of low amplitude and mixed frequencies, low chin electromyogram activity, rapid eye movements	R

*Not necessary but may be present.

AASM, American Academy of Sleep Medicine criteria (see reference 87); *EEG,* electroencephalography; *EOG,* electrooculogram; *N1,* non-REM sleep stage 1; *N2,* sleep stage 2; *N3,* sleep stage 3; *R,* REM-sleep; *W,* wakefulness.

are now available, offering the possibility of recording PSG in almost every environment, such as at the patient's home, within the hospital or nursing home room, and even within the recovery room or ICU.

Out-of-Center Testing

Portable out-of-center PSG sleep monitors are a reasonable, reliable, and effective method for diagnosing OSA[92] compared with PSG recording performed within a sleep laboratory, when applied in preselected population at risk of moderate-to-severe OSA.[92-94] The Portable Monitoring Task Force of the American Academy of Sleep Medicine (AASM) supports the use of these devices in subjects for clinical and research purposes and indicates a comparable quality of PSG data.[92]

Scoring of Sleep and Sleep Disordered Breathing

More than 40 years ago, Rechtschaffen and Kales[86] standardized the method of scoring PSG recordings—the R&K criteria. Since then, major innovations in technology have transformed the science and clinical practice of sleep medicine. The latest criteria of the AASM[87,95] capture the full potential of innovations resulting from computerization of data, including automation of sleep scoring, recognition of disorders that occur during sleep, and integration with other procedures, such as positive airway pressure titration. Although the R&K criteria are still sufficient for clinical and research purposes, they are less commonly used in sleep centers around the world.

According to these criteria, the arousal states are categorized based on the EEG activity recorded from three different scalp locations and divided into wakefulness (W), REM sleep (R), and three NREM sleep stages (Table 10.3 and see Fig. 10.1).

Respiratory events during sleep are defined as follows:

1. *Apnea* with a decrease in respiratory flow of 90% or more from baseline for at least 10 seconds, whereas a minimum of 90% of the event duration has to meet the criteria of respiratory flow reduction
2. *Hypopneas*, in which the signal of respiratory flow measurement decreases at least 30%, whereas oxygen saturation (SpO_2) decreases by 4% or more compared with pre-event baseline for at least 90% of the duration (minimum of 10 seconds). Hypopneas can also be defined as a decrease in respiratory flow measurement of at least 40% with a decrease in SpO_2 of only 3%.
3. *Respiratory event-related arousal* is defined as a series of breaths not meeting the criteria for apnea or hypopnea lasting at least 10 seconds characterized by increasing respiratory effort or flattening of the nasal pressure waveform leading to an arousal from sleep.
4. *Hypoventilations* are defined as an increase of 10% or more in arterial carbon dioxide tension ($PaCO_2$).

Although the AASM 2007 criteria[87] are commonly used in many sleep centers for clinical and research purposes all over the world, questions about whether the new criteria should be used in children[96] and the scoring of some respiratory events are still unanswered.

Sleep and Breathing

RESPIRATORY REGULATION DURING SLEEP

Sleep puts breathing at risk. The upper airway dilator muscle activity is decreased during sleep compared with wakefulness, particularly at sleep onset and during REM sleep. Furthermore, the ventilatory response to hypoxia can be impaired, such that critical hypoxia levels can occur during sleep that can be offset only by arousal from sleep.

The major determinant of minute ventilation during wakefulness and sleep is $PaCO_2$. In contrast to wakefulness, where $PaCO_2$ is maintained close to 40 mm Hg, the chemo sensitivity to CO_2 decreases during sleep, as does the chemo sensitivity for oxygen. This leads to $PaCO_2$ values of 45 mm Hg commonly occurring during stable sleep, while ventilatory demand is decreased and the arousal threshold varies with sleep stages.

Accordingly, the changes in respiratory muscle activity, ventilatory demand, and arousal threshold observed from wakefulness to sleep and across sleep stages challenge ventilatory control and can lead to instability in breathing. A structured approach to evaluating breathing instabilities is the loop gain. This engineering term is used to describe the stability of a feedback-controlled system (in this case, the chemical feedback loop controlling an individual's ventilation). In the setting of ventilatory control, loop gain reflects the propensity of an individual to develop periodic (unstable) breathing. Patients with a high loop gain caused by a more sensitive respiratory controller (i.e., high controller gain), more effective CO_2 excretion (i.e., high plant gain), or

$$\text{AHI} = \frac{\text{Apneas (10 sec without flow) + Hypopneas (reduced flow with desaturation)}}{\text{Total sleep time (h)}}$$

$$\text{RDI} = \frac{\text{Apneas + Hypopneas + Arousals (in EEG) associated respiratory event}}{\text{Total sleep time (h)}}$$

Fig. 10.7 Definition of apnea hypopnea index *(AHI)* and respiratory disturbance index *(RDI)*.

an increased delay because of slowed CO_2 distribution from peripheral tissues to the central chemoreceptors based on, for example, reduced blood circulation (i.e., mixing gain) may be more vulnerable to disturbances of the feedback system, such as slight hypoventilation that occurs as a consequence of decreased upper airway dilator muscle activity during the transition from wakefulness to sleep.

High loop gain may contribute to severity of OSA. Moreover, subjects with a high loop gain have been shown to be more likely to develop breathing instabilities such as Cheyne-Stokes respiration (CSR; see "Central Sleep Apnea").

SLEEP-DISORDERED BREATHING

SDB refers to the respiratory signs and symptoms associated with sleep-associated respiratory dysfunction and is defined by the occurrence of respiratory events, which are cessations in breathing rhythm (apneas) or momentary or sustained reduction in the amplitude of respiratory flow (hypopnea) during the sleeping state, leading to arterial hypoxemia.[97] They are usually caused either by increases in upper-airway resistance due to reduction in intraluminal airway diameter (obstructive event), marked reduction or cessation of brainstem respiratory motor output (central event), or both. A specification of SDB into obstructive or central sleep apneas (CSA) is made based on the predominant type of respiratory events. The severity of SDB is usually quantified by the number of respiratory events per hour of sleep. This is necessary because a low number of short apneas and hypopneas can occur up to about five times per hour in healthy subjects. Two measures can be used for this purpose: the apnea hypopnea index (AHI) and the respiratory disturbance index (RDI). Typically the AHI (number of hypopneas and apneas per hour of sleep; Fig. 10.7, *top*) and RDI (number of hypopneas, apneas, and arousals related to respiratory events per hour of sleep; see Fig. 10.7, *bottom*) are used to quantify the severity of SDB.

Obstructive Sleep Apnea

Definition. OSA is the most common type of SDB and is diagnosed in patients with more than 15 predominantly obstructive events per hour of sleep, or with fewer respiratory events (i.e., 5-15 per hour) if daytime symptoms (i.e., sleepiness) or comorbidities such as hypertension or atrial fibrillation are present. These cutoff values have been used as an indication for treatment by clinicians based on the clinical guidelines and the international classification of sleep disorders.[87,88] The severity of sleep apnea is further characterized as mild in patients with less than 15 events per hour of sleep, as moderate with 15 to 30 or less events per hour of sleep, and as severe sleep apnea with 30 or more events per hour of sleep (Table 10.4).[88,90]

TABLE 10.4 Severity of Sleep Apnea Based on Respiratory Disturbance Index or Apnea Hypopnea Index

	RDI (Events Per Hour)	AHI (Events Per Hour)
No sleep apnea	<5	<5
Mild sleep apnea*	≥5 to <15	≥5 to <15
Moderate sleep apnea	≥15 to <30	≥15 to <30
Severe sleep apnea	≥30	≥30

*Only diagnosed if comorbidities like hypertension, atrial fibrillation of daytime sleepiness are present.

A respiratory disturbance index (RDI) less than 5 per hour is physiologic and found in healthy humans. Sleep apnea is mild with RDI between 5 and 15 per hour, moderate with RDI between 15 and 30 events per hour, and considered severe with an RDI of 30 and greater per hour of sleep. Equal cutoff values are similar for severity based on the apnea hypopnea index (AHI).

Epidemiology. OSA with daytime symptoms affects 0.3% to 5% of the general population.[98,99] As obesity is one of the major risk factors for OSA, the prevalence might continue to increase with higher rates of obesity in the general population.[100-102] The prevalence of SDB without daytime symptoms is even higher, with rates of up to 9% in women and 24% in men between the ages of 30 and 60 years, and is often unrecognized.[103,104]

Furthermore, the prevalence of OSA varies widely between different populations. Individuals with a high susceptibility to OSA include the obese, the elderly, and those with specific comorbidities (e.g., stroke, myocardial infarction). Depending on methodology, the rates of OSA in patients following surgery is between 45%[105] and 75%.[106] A recent study in patients undergoing bariatric surgery revealed an incidence of OSA of as high as 77.5% in this population,[107] while another study showed OSA to be prevalent in 50% of women undergoing gynecologic oncology surgery [108]

Clinical Symptoms. Approximately one-third of patients with OSA complain of typical signs and symptoms occurring during wakefulness. Waking with dry mouth or headache in the morning, daytime sleepiness, falling asleep during monotonous situations (e.g., watching television), as well as subjective impairment of cognitive function are frequently reported. This combination of OSA with daytime symptoms is usually referred to as OSA syndrome.[109,110]

Sleep-associated signs and symptoms of OSA include witnessed pauses in breathing or snoring, and a high number of nocturnal awakenings, mostly reported as pseudo-nocturia. Patients with OSA occasionally complain of tachycardia or respiratory distress upon nocturnal awakening (choking sensation) and other symptoms (Box 10.1).

Consequences and Comorbidities. OSA is associated with serious medical consequences, such as hypertension, myocardial infarction, stroke,[109,111,112] diabetes, diabetic neuropathy, as well as cognitive dysfunction resulting in occupational difficulties and motor vehicle accidents.[113,114] The development of cognitive impairment in patients with OSA[115] is associated with atrophy of brain structures relevant for cognition and memory (hippocampal areas)[116] that can be partially reversed by adequate treatment.[117] Whether the negative effects of OSA are due to impaired sleep architecture or effects of intermittent hypoxia remain unclear,[118] because data investigating the effect of intermittent hypoxia without other symptoms in OSA patients are limited. Nevertheless, recent findings suggest that even asymptomatic OSA might be associated with cardiovascular effects, such as altered daytime autonomic regulation (i.e., heart rate variability).[119]

BOX 10.1 Symptoms of Obstructive Sleep Apnea

Nighttime Symptoms

- Frequent awakening during the night (e.g., pseudo-nocturia)
- Awaking from own snoring with choking sensation
- Tachycardia
- Sleep that is not restorative

Daytime Symptoms

- Awaking with dry mouth
- Dull headache in the morning
- Daytime sleepiness
- Falling asleep during monotonic situations (e.g., watching television)
- Subjective impairment of cognitive function

Symptoms Reported by Bed Partner

- Snoring, especially when loud and arrhythmic
- Observed pauses in breathing during sleep

Given the frequent rate of complications associated with OSA, it is not surprising that OSA leads to increased socioeconomic costs because of significantly more frequent rates of health-related contacts and medication use, and even higher rates of unemployment.[120]

Risk Factors. Predisposing factors for OSA are obesity,[121] age,[121,122] male sex,[121] factors leading to swelling of the superficial tissue of the upper airway (smoking),[123] allergic rhinitis,[124] and decreased muscle tone of upper airway dilator muscles (e.g., central nervous system) caused by respiratory depressants.[125]

Pathophysiology. Respiratory events during OSA are characterized by decreased respiratory flow with persisting respiratory effort due to reduced intraluminal diameter of the upper airway up to complete pharyngeal airway collapse (see Fig. 10.6). The muscles involved in respiration are morphologically and functionally skeletal muscles and can be classified into two groups: upper airway dilator muscles and respiratory pump muscles.

Upper airway dilator muscles counterbalance the negative inspiratory pressure generated by the pump muscle to permit airflow during inspiration. Respiratory pump muscles are the collection of muscles responsible for generating inspiratory and expiratory forces in the thorax across the breathing cycle (Fig. 10.8). The patency of the upper airway is maintained by balancing dilating forces (generated by the upper airway dilator muscles) and collapsing forces (i.e., negative intraluminal pressure generated by the respiratory pump during inspiration and compressive extraluminal forces from the surrounding tissues).[126]

UPPER AIRWAY DILATOR MUSCLES. The most extensively studied of the upper airway dilating muscles are the genioglossus and the tensor palatini (Table 10.5). The genioglossus receives a variety of inputs, including phasic (inspiratory) and tonic (noninspiratory) drives, which are distributed differentially across the hypoglossal motoneurons.[127] In response to negative pharyngeal pressure created by the respiratory pump during inspiration, the

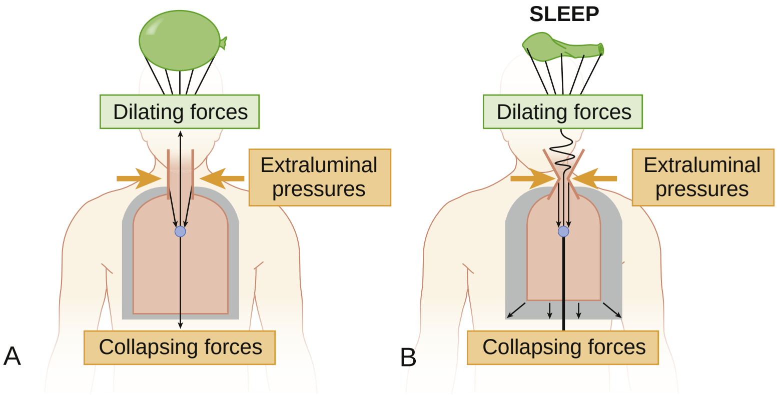

Fig. 10.8 Relationship of upper airway patency and respiratory pump activation. (A) During wakefulness, the force of the upper airway dilator muscles (*green balloon*, dilating forces) counterbalance the collapsing forces imposed on the upper airway by extraluminal pressures and negative inspiratory pressure generated by the respiratory pump muscles (represented by the orange counterweight [collapsing forces]). In obstructive sleep apnea, (B) sleep onset *(blue needle)* leads to decreased upper airway patency by reducing the dilating forces. (Modified from Sasaki N, Meyer MJ, Eikermann M. Postoperative respiratory muscle dysfunction: pathophysiology and preventive strategies. *Anesthesiology*. 2013;118:961–978.)

genioglossus reflexively stabilizes the upper airway in animals and humans.[128,129] This reflex is likely a product of signaling from inspiratory modulated motor units. Whereas the genioglossus responds to phasic input on top of its tonic activation, the tensor palatini is considered a tonic muscle with consistent tone throughout the respiratory cycle.[130]

Anatomic vulnerability to collapsing forces. The soft tissues of the pharynx are enclosed and stabilized by bony structures, such as the mandible and the spine, and complete collapse of the pharyngeal airway ordinarily requires extraluminal forces, such as hematoma, edema, peripharyngeal masses, or an airway trauma, for instance, as a consequence of prolonged endotracheal intubation.[131] Pharyngeal manifestation of obesity compresses the airway.[132] Craniofacial abnormalities can further increase the collapsing effects of excessive pharyngeal extraluminal soft tissue in obese patients.[133] The extraluminal soft tissue, as well as size and shape of the bony enclosure, are determinants of the extraluminal pressure that need to be antagonized by the upper airway dilator muscle contraction during inspiration, to avoid an upper airway obstruction–related apnea.[133] In addition, the upper airway is more vulnerable to collapse in the supine position than in the lateral or sitting positions, due to gravitational effects.[134,135]

Excessive intravenous fluid administration can affect upper airway patency. In awake, healthy volunteers, the inflation of antishock trousers displaced fluid from the lower extremities to increase neck circumference,[136] so that the upper airway had a lower threshold to collapse.[137] This concept is reinforced in studies of subjects with lower extremity venous insufficiency[138] and congestive heart failure (CHF).[139] These studies have shown nocturnal redistribution of fluid from the lower extremities into the neck increases upper airway collapsibility[138] and the severity of central apnea and OSA.[139] Similar effects may increase the risk for OSA during pregnancy and early after delivery.[139]

Another important component of airway patency is the interplay between lung volume and upper airway collapsibility. Higher end-expiratory lung volumes are associated with a decrease in upper airway resistance to airflow in awake healthy humans,[140] and an increase in upper airway lumen dimensions in subjects with and without OSA.[141] The mechanism for the interaction between upper airway patency and lung volume is thought to lie in the generation of longitudinal traction forces in the trachea.[142,143] Upon inspiration, the lung inflates and effectively forces the carina into a more caudal position, creating stretching forces on the fixed trachea.[142] These forces are transferred to the side walls of the upper airway.[143] Effectively, tracheal traction allows the respiratory pump muscles to contribute to upper airway opening.

Collapsing intraluminal pressure. The respiratory pump is the motorized action driving inspiration and expiration. It is the force that broadens the thoracic cavity and creates negative intrathoracic pressure to draw a breath in, and when needed, positive intrathoracic pressure to exhale rapidly. Inspiratory pump muscles are an anatomically diverse group, with the most studied being the intercostal muscles and the diaphragm. The diaphragm accounts for 60% to 70% of lung volume change during quiet respiration.[144] During inspiration, the volume of the thoracic cavity increases as a result of contraction of the diaphragm and the external intercostal muscles. The lungs expand secondarily to the increased negative intrathoracic pressure generated by these phasic actions of the inspiratory pump muscles. The negative intrathoracic pressure translates into a negative intraluminal pressure in the upper airway, forcing the airway to collapse as soon as this pressure drops below a critical value.[145]

Although this critical airway pressure (Pcrit) is typically negative (approximately −5 cm H_2O) in healthy controls, the upper airway in patients with OSA during sleep may even collapse at a positive Pcrit. Positive intraluminal pressure is required for reopening the paralyzed airway in patients with OSA.[146] Under normal conditions, the two compressing factors, (1) negative intraluminal pressure and (2) positive extraluminal pressure, need to be actively compensated by muscular activity of the upper airway dilator muscles to maintain airway patency.[97]

Wakefulness stimulus and sleep. Excitatory inputs to the upper airway motoneurons (e.g., hypoglossal motoneurons) include those from serotoninergic and noradrenergic neurons that fire predominantly during wakefulness,[147-150] resulting in a “wakefulness stimulus” that increases the activity of upper airway dilator muscles during this arousal state. With onset of sleep, this arousal-dependent neuronal input (active while awake versus less active, or inactive when asleep) disappears, leading to a decrease in upper airway muscle activity and causing increased upper airway resistance in healthy controls and airway collapse in patients with OSA.[151-153] The resulting retropalatal obstruction of the upper airway is reported to be the most common pathophysiological mechanism in OSA.[146]

One way valves in the upper airway. Observing the respiratory flow tracings in patients with OSA, one can find some respiratory events that do not show the characteristic progressive flow limitation ultimately resulting in complete upper airway occlusion, typically seen as a result of “collapsible tube pathophysiology” with variable compliance. In these cases, the flow tracings show normal expiratory flow and sudden reduction/cessation before reaching maximum inspiratory flow. This “rapid obstruction” only during the inspiratory phase occurred in approximately 20% to 30% of OSA patients.[154] Recent findings suggest that there are two one-way valves in the pharynx. While the epiglottic valve closes during inspiration, the soft palate may function as a second one-way valve limiting flow during expiration.[155]

Similar to the epiglottis, the soft palate hangs from the hard palate like a peninsula in the oropharynx and might

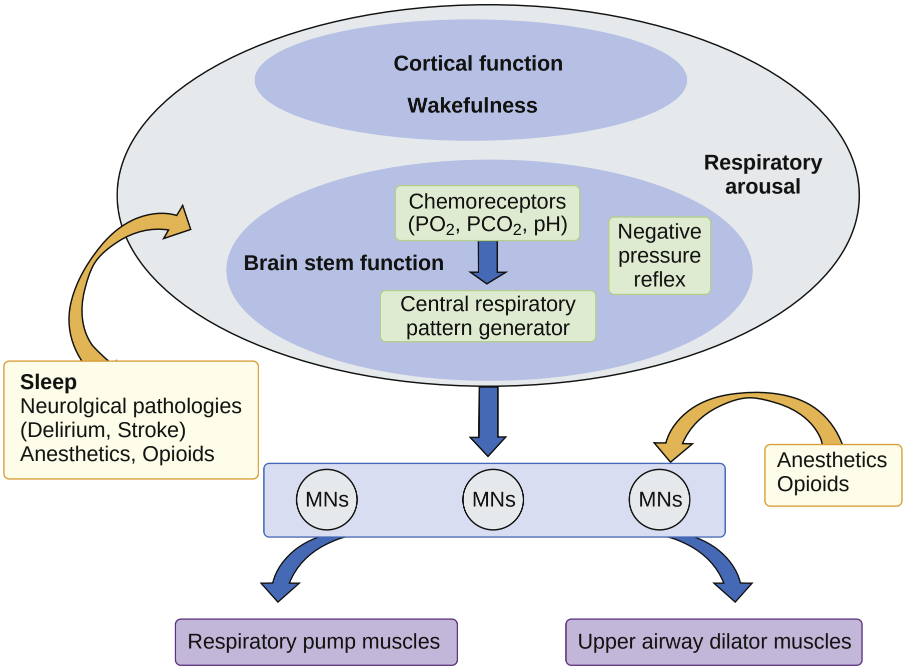

Fig. 10.9 Effects of respiratory arousal on upper airway dilator and respiratory pump muscles. Respiratory arousal is composed of three primary inputs: central respiratory pattern generator processing peripheral and central chemoreceptor afferents, reflex responsiveness to the magnitude of negative pressure in the airway generated by the respiratory pump muscles, and strength of the wakefulness stimulus. Different factors can impair respiratory arousal, such as sleep and neurologic pathologies, anesthetics, and opioids. Blue arrows indicate excitatory effect; yellow arrows indicate inhibitory effect. *MN*, Motor neuron. (Modified from Sasaki N, Meyer MJ, Eikermann M. Postoperative respiratory muscle dysfunction: pathophysiology and preventive strategies. *Anesthesiology*. 2013;118:961–978.)

occlude the upper airway during expiration.[156] A recent study found that sudden reduction of expiratory airflow immediately after peak expiratory flow occurs more often in OSA patients under positive pressure ventilation.[157] Similar expiratory flow limitation pattern was also reported in spontaneously breathing OSA patients, suggesting that this phenomenon is not unique to positive pressure ventilation.[158]

These findings may point to a second, slightly different mechanism underlying OSA than the pure collapsible tube pathophysiology in some OSA patients, which should be particularly important during anesthesia. Correct identification of the closure site in each OSA patient will enable the clinician to provide an individualized OSA treatment.[155]

RESPIRATORY AROUSAL. Respiratory arousal is arousal from sleep owing to cumulative and progressive increases in stimuli related to breathing (hypoxia, hypercapnia, and respiratory effort).[159]

Three primary inputs contribute to arousal-related restoration of breathing following an apnea (Fig. 10.9):

1. Peripheral and central chemoreceptors sensitive to partial pressures of oxygen and carbon dioxide[160]
2. Sensors in the upper airway responsive to negative pressure generated by the respiratory pump[128,129]
3. Cortical inputs directly related to state of consciousness or wakefulness[161]

Any of these inputs can restore respiratory muscle tone if the magnitude of stimulation is sufficient. Cortical awakening from sleep, identified by EEG signs of wakefulness, is an adequate stimulus for ventilation. However, obstructive apneas, such as upper airway collapse in OSA, can be terminated by an increased drive to the respiratory muscles not involving cortical arousal.[162] For example, hypercarbia resulting from sustained hypopnea[160] and elevated upper airway negative pressure[128,129] can independently restore tone to the respiratory muscles. The level of drive provided to the respiratory muscles depends on the summation of stimuli in the central respiratory pattern generator output, including peripheral and central chemo-responsiveness, reflex responsiveness to the negative airway pressure, and strength of the wakefulness drive.

Treatment. Adequate treatment of OSA improves nocturnal oxygen saturation as well as duration and quality of sleep, which translates to reduced daytime sleepiness, improvement of daytime functions, and improved quality of life. Successful treatment of OSA reduces cardiovascular risk, improves insulin sensitivity, and increases neurobehavioral performance.[163-165] Therefore, all patients with a diagnosis of OSA should be offered treatment as soon as the diagnosis of OSA has been established and its severity has been determined by objective testing (i.e., PSG).[88] Although different treatment options for OSA have been developed during the last decades (Table 10.6), continuous positive airway pressure (CPAP) dose dependently increases upper airway diameter and is still the most effective treatment for OSA of all severities.[166-168] However, a recent study has questioned if CPAP treatment is able to prevent the long-term adverse cardiovascular events in OSA.[169]

POSITIVE AIRWAY PRESSURE TREATMENT. CPAP as a treatment for SDB is typically applied continuously with a nasal or oronasal mask, and can dose dependently reverse any sleep-associated upper airway obstruction, as outlined in Fig. 10.10. The CPAP level needed for treatment of OSA

varies mostly between 5 and 20 cm H_2O. However, home RP and titration of CPAP might be similarly effective in some but not all patients with suspected OSA.[176,177] After titration, the prescribed treatment pressure is applied continuously throughout the night. Although this treatment is efficient in reversing the underlying pathology, the impact of CPAP on outcome is limited by patient adherence,[112,178] mostly because of local side-effects at the nose or face, or discomfort caused by the mask.[179] When applied with high pressure, the amount of airflow can prevent the patient from falling asleep while using the treatment device. Some treatment devices offer a ramp or delay function that gradually increases treatment pressure from a low starting pressure to the prescribed pressure over a period of 5 to 45 minutes, allowing the patient to fall asleep more easily. Some patients report difficulties exhaling against high CPAP. To avoid this problem, bilevel treatment with reduced expiratory positive airway pressure and a sufficiently high inspiratory positive airway pressure can be used.

In some cases, one CPAP pressure level is not sufficient to treat sleep apnea. CPAP devices with dynamic pressure levels can improve treatment success, particularly in patients with a variable severity of sleep disordered breathing during different sleep stages. These automatic positive-airway pressure or auto-titrating devices measure different variables associated with hypopnea, such as oropharyngeal wall vibration, snoring, and inspiratory flow limitation, and increase the airway pressure until these signs and symptoms of hypopnea disappear. In addition, it is not entirely clear whether CPAP treatment is able to prevent the increased cardiovascular risk inherited by OSA.

CPAP is sufficient in the treatment of most patients with OSA. However, some patients may need different treatment methods. For example, patients with mixed apneas (obstructive and central) or predominantly central apneas need a more controlled (frequency or time controlled), noninvasive ventilation (NIV) with predefined minimal respiratory frequency or respiratory timing that automatically induces the next inspiration (ventilation) if the patient does not induce the next breath within preset parameters.

Alternative treatment options. Oral appliances (OAs) are possible treatment options in patients with mild to moderate OSA who do not tolerate CPAP therapy. Two major designs are currently used clinically: (1) mandibular repositioning appliance, which holds the mandible in an advanced position (a protrusion of at least 50% of the maximal possible extension is recommended for effective treatment),[179] and (2) tongue-retaining devices, leading to repositioning of the tongue into a forward position without any protrusion of the mandible. A multidisciplinary

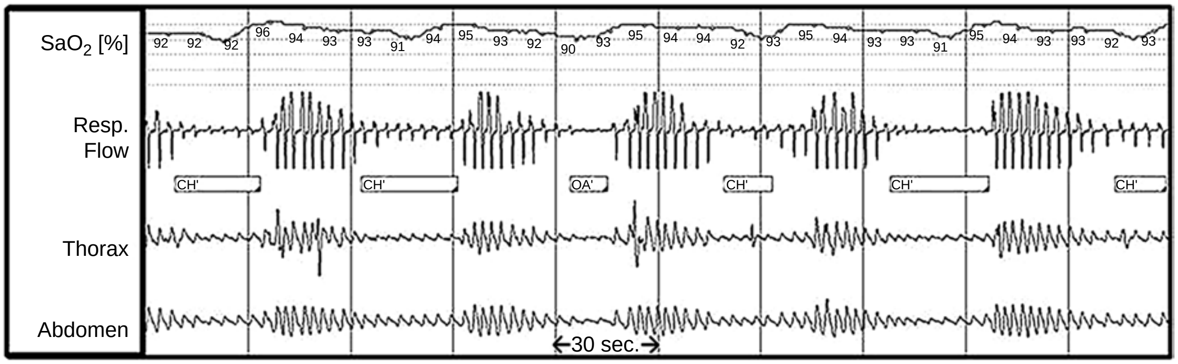

Fig. 10.11 Polysomnographic recording of an episode of Cheyne-Stokes respiration. *CH,* Central hypopnea; *OA,* obstructive apnea.

approach including a sleep physician and a dental technician experienced in OAs has been recommended for this purpose, because both factors are crucial for patient adherence and outcome from OA treatment.[109] OAs are recommended in patients with mild to moderate OSA who do not tolerate,[179] do not respond to, fail, or are not appropriate candidates for CPAP treatment.[88]

Historically, surgical treatment methods were the only approach to treatment of OSA, but the effectiveness of most of the nasopharyngeal surgical approaches for severe OSA remains unclear. However, tonsillectomy is beneficial in adult patients with OSA from tonsillar hypertrophy, and adenotonsillectomy is recommended in children with OSA and adenotonsillar hypertrophy.[180] Repeated sleep testing before and following surgery is recommended to ensure sufficient long-lasting therapeutic effects.[88,179,181]

Electrical stimulation of the upper airway muscles has been explored recently as a new approach to treatment of OSA. Hypoglossal nerve stimulation induces genioglossus muscle contractions, which dose dependently increase inspiratory airflow during OSA,[182] but the invasiveness of the procedure, the cost of the device, and the requirement for preimplantation endoscopy during anesthesia limit its use as a first-line treatment of OSA.[149]

While pharyngeal fat deposits led to a decrease in pharyngeal patency, underlining the risk factor of obesity,[183,184] weight loss leads to a reduction in Pcrit and the severity of OSA[145,171] and is recommended as adjunctive treatment in all overweight patients with OSA.[185] Because long-term weight reduction is more effective when accompanied by weight loss surgery, bariatric surgery may be considered as an adjunctive therapy in very obese patients (body mass index [BMI] ≥ 40 kg/m^2), as well as in those with important comorbidities and BMI of 35 kg/m^2 or greater and in whom dietary attempts at weight control have been ineffective.[88]

Oxygen is currently not recommended as primary treatment of OSA, but may be used as an adjunctive treatment in some patients, particularly in the postoperative period.[88,186]

Although OSA is more common in the older population, it occurs in children with a peak in the incidence between 2 and 5 years of age. Obesity predicts snoring and other signs of obstructive respiratory events in children.[109] Tonsillar and adenoidal hypertrophy is another important cause of OSA in children and can be treated surgically.[187]

Central Sleep Apnea

CSA impairs quality of life[188] and is associated with adverse outcome in heart failure patients.[189,190] CSA is defined as cessation of air flow without respiratory effort,[188] which separates it from OSA, where respiratory effort is maintained or even increased during an apnea. In clinical sleep apnea, considerable overlap between OSA and CSA occur that need to be identified and subsequently treated.[191]

CSA can be found in older patients and in patients with severe comorbidities such as CHF, stroke, or other neurologic disorders (e.g., amyotrophic lateral sclerosis). In a southern Pennsylvania cohort, CSA (AHI ≥ 20/hour) was found in 5% of men aged 65 years and older, but it was not found in younger men or in women of any age. For an AHI of 2.5 per hour and greater, the prevalence estimates in men younger than 45 years remains negligible, while CSA was found in 1.7% of men between 45 and 64 years, and 12% in men older than 65 years,[192] or 9% in individuals between 40 and 97 years, respectively.[193]

CSA mechanisms can be categorized into those with high and low loop gain. The most common subtype of CSA with an increased loop gain is CSR and is commonly seen in patients with CHF and left-ventricular systolic dysfunction. CSR is defined as a crescendo-decrescendo pattern of hyperventilation between 20 and 30 seconds in duration, followed by 10 to 40 seconds of hypopneas or apneas (Fig. 10.11), usually occurring during NREM sleep stage 1 and 2.[194] Nevertheless, CSR can also occur during exercise or wakefulness. Nearly one out of two patients with CHF shows CSR.[195] CSR is more common in men and worse in the supine body position.[161]

Potential respiratory therapies of CSR include oxygen, respiratory stimulants (e.g., CO_2, theophylline, and acetazolamide), and NIV such as bilevel positive airway pressure. The effectiveness of CPAP as therapy is controversial. Optimization of medical therapy is the best treatment, because CSR will often resolve with adequate treatment of CHF (cardiac resynchronization therapy and surgical treatment, such as heart transplant).[194]

Other Forms of Central Breathing Disorders. The term *periodic breathing* refers to altitude-induced breathing instability that occurs in subjects transferred to a high altitude, where ambient hypoxia caused by low barometric pressure leads to an increase in controller gain.[97] Idiopathic CSA, which is a relatively uncommon disorder at sea level, occurs more likely in individuals with an elevated hypercapnic ventilatory response (high controller gain) that leads to hypocapnia and respiratory control instability during sleep. Patients with idiopathic CSA tend to have low $PaCO_2$ levels, even during wakefulness.[196]

Obesity Hypoventilation Syndrome

Alveolar hypoventilation is defined as insufficient ventilation leading to hypercapnia (increased $PaCO_2$). Mechanisms of alveolar hypoventilation include central hypoventilation, chest wall deformities, neuromuscular disorders, chronic obstructive pulmonary disease, as well as severe obesity (obesity hypoventilation syndrome [OHS]). OHS is defined as the combination of nocturnal and daytime hypoventilation, usually leading to hypercapnia in obese subjects (BMI $\geq$ 30 kg/m^2), in the absence of other causes of hypoventilation.

The prevalence of OHS is estimated to be up to 50% in obese patients with OSA. It can occur in up to 50% of patients with a BMI of 50 kg/m^2 or more,[197] compared with 0.15% to 0.3% in the general adult population. Ninety percent of patients with OHS also suffer from OSA.[198,199] OHS often remains undiagnosed, and the true prevalence remains unclear.

Severe obesity is associated with an increase in respiratory drive that helps maintain eucapnia in the presence of the abnormal chest wall mechanics and high work of breathing.[200,201] In OHS, this compensatory mechanism is abolished,[201,202] which in part might be explained by leptin resistance.[203-205] Typically, OHS manifests as a reduced lung capacity, vital and functional residual capacity, expiratory reserve volume, respiratory system compliance, and inspiratory muscle strength, whereas response to CO_2 might be reduced or normal. In addition, there is an increase in serum bicarbonate and alveolar PCO_2, as well as in the work of breathing and leptin levels.[205,206]

Impairment of the effectiveness of respiratory pump muscle function in patients with OHS can be explained by the effects of low lung volume because of central fat distribution, leading to a cranial displacement of the diaphragm when lying supine.[206,207] In addition, diaphragmatic myopathy might be a contributing factor of OHS.[205] Treatment options include weight loss and NIV.[207,208]

Sleep and Anesthesia: Two Unequal Twins Influencing Perioperative Medicine

CLINICAL PICTURE OF SLEEP AND ANESTHESIA

Although physiologic sleep and anesthesia share some clinical features (loss of consciousness and a modulation of brainstem autonomic function), major differences can be found when closer observations of both behavioral states are undertaken. In contrast to anesthesia, sleep shows spontaneous generation and termination, ready reversibility by noxious stimuli, and homeostatic regulation. Anesthesia does not share the stage-wise structure seen during physiologic sleep. In addition, functional imaging studies underline the fundamental differences during onset of anesthesia and wakefulness-sleep transition.

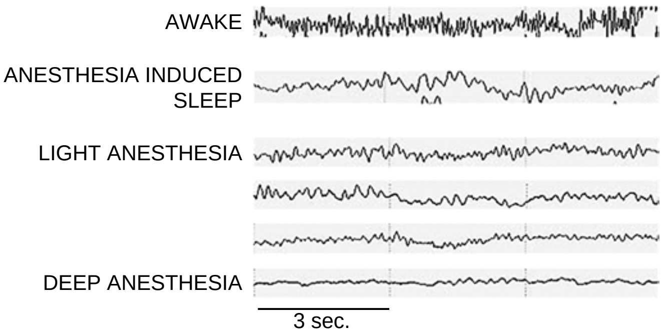

Fig. 10.12 Electroencephalographic recording during sedation and loss of consciousness induced by propofol. Compared with physiologic sleep (see Fig. 10.1), sedation shows electroencephalographic (EEG) traces comparable to slow wave sleep, indicating the sleep-inducing effect of anesthetics. Anesthesia-induced loss of consciousness (lower four traces), shows different EEG activity with reduced amplitudes and burst suppression. (Burst suppression is not shown in these traces.)

Although there are similarities in the EEG patterns between slow-wave sleep and anesthesia-induced unconsciousness, the EEG patterns during sleep and anesthesia are different,[209] with different frequencies and types of activation in EEG recorded during physiologic sleep and the uniform EEG picture observed during anesthesia-induced unconsciousness (Fig. 10.12).[210]

During anesthesia induction, the level of consciousness continuously decreases from fully awake through states of reduced response to external stimuli up to a completely unresponsive state.[211] This is in contrast to the sharp α–θ EEG transitions seen while an individual proceeds from wakefulness to sleep without any transient stages. Individuals in a steady state of physiologic sleep can be aroused with sufficient stimulation, whereas drug-induced unconsciousness needs at least some drug elimination to occur before individuals can be aroused.[212]

ACTIVATION OF SLEEP-PROMOTING PATHWAYS DURING ANESTHESIA

The role of the endogenous sleep-promoting system in the mechanism of action of general anesthetics has recently received much attention. This hypothesis is attractive because of the similarities of sleep and anesthesia and some evidence that anesthetically induced sleep could meet some of the homeostatic need for sleep.[213,214] It is even more attractive because, despite the large database of the molecular effects of anesthetics, how loss of consciousness occurs is still not explained. An important discovery is that some of the neurons that are active during sleep in the VLPO are also activated by certain anesthetics.[213-216] A second key observation is the inhibition of the arousal nuclei, the TMN, contributes to anesthesia.[215] This effect also implicates activation of VLPO because it provides the major source of inhibition of the TMN. The idea has emerged that anesthesia-induced loss of consciousness is mediated by effects of the anesthetics on the flip-flop switch centered in the VLPO that is responsible for the sharp transition from wakefulness to sleep and back (see earlier section).[212,217,218] However, there are a number of problems with this theory, including that rats and mice with complete lesions of the VLPO can still be anesthetized.[216,219] Although lesions of VLPO lead to a transient resistance to volatile anesthetics,[216] if some time elapses following a VLPO lesion, the animals show increased sensitivity to isoflurane anesthesia attributable to increased homeostatic sleep drive.[216,219-221] Another problem with the VLPO-TMN circuit hypothesis of anesthesia is that direct inhibition of the TMN produces sedation but not anesthesia.[215] Animals without VLPO neurons have profound insomnia. Therefore, interaction of anesthetics with these sleep-promoting nuclei alone is not sufficient to produce unconsciousness during anesthesia. During recent years, several studies provided evidence to extend the scientific framework of general anesthetics modulating sleep-promoting regions by the anesthetic depression of arousal-promoting nuclei, including the LC, GABAergic neurons of the pontine reticular formation, the pedunculopontine and laterodorsal tegmentum, the ventral tegmental area, as well as the perifornical area, the tuberomammillary nucleus, and the basal forebrain.[222,223] This "bottom-up" hypothesis of anesthesia-induced unconsciousness may be the result of the simultaneous interaction with the brainstem and diencephalic regions, including the AAS and endogenous sleep circuitry. Although, these mechanisms show similarities with sleep-promoting neuronal interactions, they are unlikely to be the only correlate of anesthesia-induced unconsciousness. Sleep, but not anesthesia, is easily reversed or prevented by real or perceived environmental threats. While interaction with sleep-promoting neurons work by inhibiting these arousal pathways, other neuronal networks crucial for consciousness (e.g., thalamocortical networks) remain active during sleep.[224] However, the finding that many anesthetics engage sleep pathways is still important and meaningful, as this is undoubtedly an important mechanism by which these classes of anesthetics promote sleep. Nevertheless, this effect does not and cannot prevent arousal to sufficient external stimuli. The unique property of anesthesia to do so has to be mediated by an additional mechanism.

PERIOPERATIVE INTERACTIONS BETWEEN ANESTHESIA AND SLEEP

Anesthesia and painful surgical procedures affect sleep and circadian rhythms[225-227] for as long as 6 months, depending on the complexity of the procedure performed.[228] A substantial decrease in REM sleep occurs on the first night after surgery and anesthesia, followed by a profound REM rebound phenomenon on the second to fourth postoperative nights, when REM sleep increases in both intensity and amount.[225,227] Although most anesthetics can lead to an impairment of sleep architecture, such as REM depression and reduced sleep quality during the early postoperative period, the extent of this impairment probably depends on the pharmacokinetics and pharmacodynamics of the anesthetics and opioids used,[229,230] which affect the duration of REM sleep,[231,232] as well as surgery-induced stress.

The effect of propofol on sleep architecture and REM sleep is complex and dose dependent. In long-term ventilated, critically ill patients, propofol sedation abolishes REM sleep and diminishes sleep quality,[233] whereas with low-dose propofol, REM sleep is possible. The effects of ketamine sedation on sleep architecture have not been studied in detail, although it may have rather mild effects on REM duration.[234]

Anesthetics have strong effects on GABA and NMDA receptors, both of which are linked with circadian control. As a result, anesthetics may interfere with entrainment of the circadian rhythm; however, preclinical and human data show inconsistent results. A recent trial in honeybees suggested an anesthetically induced circadian shift. Inside the laboratory with no outdoor cues, daytime anesthesia disturbed the usual activity patterns in the hive for the next several days. In addition, cycles of clock gene activity showed a delay,[235,236] and inhibition of the period circadian protein (per)-2 gene expression (one of the core clock genes) was observed during anesthesia.[237] Of note, psychotropic nonanesthetics, such as opioids, have been shown to affect melatonin secretion indirectly, independent of the behavioral state anesthesia in a pig model.[238] Previous work in humans has shown that 3 hours of anesthetic exposure does not affect the circadian phase of the body temperature rhythm.[239]

In summary, the specific mechanisms of anesthetics effects on circadian rhythm are unclear. The ability to distinguish between effects occurring directly on the circadian pacemaker and those occurring downstream from the pacemaker on other physiologic control systems requires additional research under rigorous experimental conditions.

Surgical treatment itself impairs sleep, expressed as reduced REM sleep duration even in the absence of general anesthesia.[229,230] Pain, inflammation, stress immobility, and anxiety seem to be contributing factors.[240] After surgery, patients show a significant impairment of sleep quality and duration. Eventually, it will be known whether specific anesthetics are preferable to avoid the adverse effects of sleep deprivation.

SLEEP-DISORDERED BREATHING AND AIRWAY PATENCY DURING ANESTHESIA
